Chemical Engineering

METALLURGICAL AND CHEMICAL ENGINEERING

A Monthly Journal being the Incorporation of
Electrochemical and Metallurgical Industry
and Iron and Steel Magazine.

VOLUME X

From January to December 1912

436835
3. 7. 45

NEW YORK:
ELECTROCHEMICAL PUBLISHING CO.

V.10

INDEX TO VOLUME X

GENERAL ALPHABETICAL INDEX

Entries from the Synopsis of Periodical Literature are indicated by S. (Synopsis); from the Analysis of Current Electrochemical, Chemical and Metallurgical United States Patents by P. (Patents); from the Digest of Electrochemical United States Patents Prior to July, 1902, by D. (Digest).

A

Abbe Engineering Co. ... 445
Abbe, Paul O. ... 445
Abrasion and dust losses in ore drying. Dietz and Keedy. (S.) ... 558
Acid-proof linings of bakelite ... 53
Acids. Chemically pure. Manufacture. Baker ... 719
Adobe as building material ... 659
Agglomeration of fine materials. Landis ... 164
——(See also Blast Roasting Briquetting ing.)
AGITATOR:
——Application of compressed air. Trent. (S.) ... 429
——Mechanical design ... 538
——Hafer. (P.) ... 306
——Hammond. Pulp. (P.) ... 489
——Parral tank. MacDonald ... 48, 434
——and classifier. Fairfield. (P.) ... 177
Agricultural chemistry ... 609, 625, 636
Air, compressed for pumping. Abrams ... 316
——for agitation. Trent ... 429
Air-lift system of pumping. Abrams ... 319
Air-Blast Heater. Hohmann (P.) ... 820
Air. Measuring small quantities of low-pressure air. Wenzouth. (S.) ... 315
Air. Saltpeter. (See Nitrogen atmospheric fixation.)
Alaska outlook ... 563
Alcohol from paper mill wastes ... 401
Aldehydes. Determination ... 605
Alderson, Victor C. ... 446
Alkali-proof ebonite. Wilderman ... 629
Allgemeine Elek. Ges. ... 501
Allotropy of iron and silver iodide. Benedicks ... 692
ALLOYS:
——Aluminium. Wilson. (S.) ... 756
——Aluminium. Deterioration ... 749
——Aluminium and zinc ... 424
——Anticorrosive. Jacquier. (P.) ... 308
——Cobalt-chromium. Haynes ... 804
——Coinage alloys. Annealing. Rose ... 724
——Copper. Tensile tests at higher temperatures. Huntington ... 724
——Copper-zinc. Bancroft and Lohr ... 690
——Copper-zinc. Inversion. Carpenter. 224
——Copper-zinc. Jones. (P.) ... 816
——Copper-zinc. Microstructure. Carpenter ... 725
——Copper and zinc simultaneously deposited by electrolysis. Thompson ... 458
——Electrolytic Refining. Betts. (P.) ...
——Eutectic alloys for production of porous storage battery plates. Hannover ... 509
——Heating in Vacuo. Turner ... 225
——Heusler. Take and Heusler ... 403
——Heusler. Magnetic properties and microstructure ... 403
——Influence of oxygen on properties. Law. ... 725
——Iron-carbon and iron-silicon. Magnetic properties. Gumlich ... 402
——Iron-nickel. Non-corrosive. Carnaban. (P.) ... 818
——Iron-nickel-copper. Clamer. (P.) ... 308
——Iron-nickel, iron-cobalt, nickel-cobalt Magnetism. Weiss ... 404
——Magnesium-casting. Hoffman and Suchy. (P.) ... 491
——Magnetic properties ... 402
——Manganese Bronze. Corse and Skillman ... 595
——Measurement of compressive strength. Huber ... 96
——Nomenclature. Rosenhain ... 226
——Properties at high temperatures. Bengough ... 225
——Pyrophoric. Krieger. (P.) ... 375
——Lesmüller. (P.) ... 375
——Silver-bismuth. Refining. Lacey ... 747
——Substitute for brass. Gross. (P.) ... 375
ALLOYS: (Continued.)
——Temperature and strength ... 160
——(See also brass and ferroalloys.)
ALUMINA:
——as drying agent. Johnson. (S.) ... 755
——Cowles process ... 659
——in copper slag formation. Bellinger. (S.) ... 693
——Buchanan and Lee ... 795
——in iron blast-furnace slag. Johnson. 812
——Nitrogen fixation by alumina and carbon. Tucker and Read ... 745
——potash, alumina, silica from feldspar. Hart ... 634
ALUMINIUM:
——Advances in metallurgy ... 650
——Alloys. Light. (S.) ... 756
——Alloys deterioration ... 749
——Alloys with zinc ... 424
——Alloy with titanium. Rossi. (P.) ... 308
——Electric equipment of Whitney, N. C., plant. ... 763
——for water purification ... 351
——in France ... 655
——International aluminium syndicate ... 425
——Oxy-acetylene welding. Carnevali ... 726
——Pickling before plating. Jahn. (P.) ... 552
——Plant in Whitney, N. C. ... 445
——Serpek process ... 255
——Solder. Erkens. (P.) ... 556
——Solder. Hartmann. (P.) ... 309
Alundum refractory. Boeck ... 581
——Fitz Gerald ... 129
Alundum extraction thimble for copper determination. Bahney ... 737
Alunite. Source of potash. Waggaman. 734
Amalgamated Copper Co. ... 11
AMALGAMATION:
——Electrolytic. Alling. (P.) ... 51
—— Andreoli. (D.) ... 765
—— Danckwardt. (D.) ... 122
—— Edwards. (D.) ... 62
—— McNulty. (D.) ... 765
—— Pelatan and Clerici. (D.) ... 122
—— Potter. (P.) ... 752
——Amalgamator for gold. Frey. (P.) ... 552
——(See also Gold and Silver.)
Amalgams. Thallium. Richards and Daniels ... 619
Amalgams. Vapor pressure and e.m.f. ... 619
American Carbon & Battery Co. ... 121
American Chemical Society. Washington meeting ... 66
American Cyanamide Co. ... 667
American Electrochemical Society, 66, 126, 194, 390, 710, 745
——Assisted research fund ... 406
——Boston meeting ... 257, 285
American Foundrymen's Association. Buffalo convention ... 702
American ingot iron for metallic roofing. Aupperle ... 57
American Institute of Chemical Engineers, 8, 10, 710, 770
——Proposed code of ethics. Richards ... 776
American Institute of Metals, Buffalo Convention ... 702
American Institute of Mining Engineers, 66, 710
——Cleveland meeting ... 801
——Iron and steel division ... 326
——Japan excursion ... 15
——New York meeting ... 161
——Situation in Stone and Corning ... 512
American Iron and Steel Institute ... 710
——Electric steel refining ... 371
——Pittsburgh meeting ... 772
American Museum of Safety ... 113
American Rolling Mill Co. ... 444
American Vanadium Co. ... 237, 763
American Zinc, Lead & Smelting Co. ... 377
Ammonia. Synthetic. Bernthsen ... 637
Ammonium sulphate from ammonia and sulphur dioxide from coal gases. Feld. ... 395
Anaconda. Chemistry of reduction processes. Laist ... 592
ANALYSIS:
——Alundum extraction thimble for copper determination. Bahney ... 737
——Barium ... 645
——Combined potash bulb and drying tube. Vanier ... 380
——Combustion train for electric furnace. Vanier ... 380
——Compressed oxygen for estimating carbon in ferroalloys ... 750
——Cupellation of silver-lead buttons. Benner and Hartmann. (S.) ... 246
——Determination of methane in producer gas. Arndt ... 391
——Electro-analysis with acidified chloride electrolytes. Schock and Brown ... 684
——Electrolytic assay of gold solutions. Crighton. (S.) ... 120
——Electrolytic determination of lead ... 108
——Electrolytic, of lead. List ... 135
——Errors in gas analysis. Burrell and Seibert ... 690
——Free sulphur in spent oxide ... 174
——Gas analysis. Williams ... 382
——Hydroxide reactions ... 645
——Light platinum electrodes. Gooch and Burdick. (S.) ... 559
——Manganese ... 645
——Methods of sampling and analysis. U. S. Steel Corporation ... 650, 668
—— Ores containing the platinum group metals. Dart ... 219
——Oxalate-permanganate method for determining copper ... 377
——Oxygen in iron. Walker and Patrick ... 629
——Pig iron. U. S. Steel Corporation ... 668
——Precipitation of ammonium sulphide group of metals ... 645
——Quick combination methods of assays. Levings ... 549
——Refined in ore testing ... 449
——Samples. Preparation. Blyth. (T.) 815
——Silver ores containing cobalt, nickel and arsenic. Handy ... 688
——Standard methods of sampling for check analysis. Association of American Steel Manufacturers ... 701
——Sulphur in oils ... 635
——Strontium ... 645
——Typical analyses of iron blast-furnace gases ... 713
——Water in petroleum ... 635
——Zinc dust. Sharwood. (S.) ... 376
Analytical chemistry at congress, 604, 615, 623, 635, 645
Annealing of coinage alloys. Rose ... 724
Annealing low-carbon steel. Coarse crystallization. Sherry ... 666
Antimony by electrolysis from sulphide. Engelhardt and Nettel. (D.) ... 502
——Electrolytic process. Engelhardt. (D.) 188
——from stibnite. Fink ... 296
——in tough-pitch copper. Johnson ... 726
Argall, Philip ... 61, 187
Arizona Copper Co. ... 196
Arsenic. Electrolytic process. Engelhard (D.) ... 188
Arsenic ores. Vacuum furnace treatment. Fink ... 296
Arsenical silver ore. Treatment. Fink. (P.) ... 177
Arsenous chloride. Volatility ... 605
Asphalt ... 614, 635
Asphalt ... 635
Assay. (See Analysis.)
Association American Steel Manufac- Standard methods of ling for check analysis ... 701
Atlas Dryer ... 798
Atmospheric nitrogen fixation. (See Nitrogen fixation.)
"Atomized" lead and zinc for precipitation of gold and silver. Neil. (P.), 180, 431
"Atomized" lead and zinc. Neil (P.) 181, 305
Atomic weights ... 623

B

BAEKELAND, L. H. Portrait.....584, 596
Bag house for recovery of lead fumes. Eilers. 588
Bag house. Shaking the bags. Meier. (P.) 555
Bakelite for acid-proof linings and other chemical purposes 53
Baker, J. T., Chemical Co..... 108
Balance. Specific gravity..... 605
Balancing chemical equations. Wilson.. 94
Balling scrap iron. Lentz. (P.)..... 247
——Sellers and Nicholls. (P.)..... 487
Balling. (See also Agglomeration, Blast Roasting, Briquetting, Sintering.)
Ball Mills. Shepard..... 216
Bamboo cellulose 609
Bancroft, W. D. Portrait..... 605
Bartley, Jonathan, Crucible Co..... 182
Battelle & Renwick 762
Bausch & Lomb Co..... 445
Beck, Erich A..... 321
Beehive coke ovens..... 645
Belt conveyors. Moss..... 346
Benner, R. C..... 703
Bethlehem Steel Co. Electric steel refining 509
Biddle, James G..... 252
Bigelow, W. D. Portrait..... 604
Bignell, L. G. E..... 384
Biochemistry at congress.....615, 626
Bioelectric potential differences. Bentner. 619
Biological chemistry. Infinitely small quantities. Bertrand 598
Bismuth-silver alloys. Refining. Lacey. 747
"Black Body." Shook..... 238
Black-body standards. Shook..... 416
BLAST FURNACE:
Air-blast heater. Hohmann. (P..)..... 820
——Alumina in slag. Johnson..... 812
——American water-jacket lead blast furnace. Canby..... 596
——Blowing in. Sweetser..... 803
——Charging apparatus. Baker. (P.)... 305
——Charging device. Roberts. (P.)..... 554
——Charging fine ore and dust. Dougherty. (P.) 432
——Construction. Ladd and Baker. (P.). 487
—— McMurray. (P.)..... 488
—— Roberts. (P.) 487
——Design at Granby copper smelter. Lee. 149
——Direct and indirect reduction. Levin. 420
——Drying air by refrigeration for dry blast. Walter and Currier..... 471
—— Smith 657
——Enriching blast with oxygen. Jenkins. (P.) 247
——Purification of gases by Feld centrifugal gas washer..... 436
——Blast furnace and sky-scraper on fire. Analogy 64
BLAST ROASTING:
——Galena. Bannister. (S.)..... 246
——Greenawalt down-draft pan. Pulsifer. 207
——Huntington-Heberlein pots. Pulsifer. 157
——Important factors. Pulsifer....153, 207
——Savelsberg converters. Pulsifer.... 158
——(See also Briquetting, Sintering.)
Bleaching powder. R. L. Taylor..... 256
Bleaching powder for production of oxygen. Neumark 109
Blower, pressure 445
Blowpipe. First injector type..... 70
Blowpipe for oxy-acetylene welding. Reich. 442
Blue powder. Electrolytic reduction. Bleeker 300
——(See also Zinc.)
Bogert, M. T. Portrait..... 593
Boilers. Action of caustic soda..... 46
——Reduction of heat-conducting surface. 438
Bolting cloth 445
BOOK REVIEWS:
——Abegg, Auerbach and Luther. Messungen Elektromotonischer Kräfte galvanischer Ketten. 256
——Annual tables of constants and numerical data, chemical, physical and technological.....572, 766
——Bender, Der Praktische Hochofenbetrieb 504
——Billiter, Die eletrochemischen Verfahren der chemischen Gross Industrie 384
——Billiter, Die elektrolytische Alkalichloridzerlegung mit Starren Metallkathoden 504
——Brearley. Heat treatment of tool steel 190
——Burgess & Le Chatellier. Measurement of high temperatures.... 448
——Byers & Knight. Notes on quantitative analysis 705
——Caldercott, Smale, Thomas, Hawkes, Dowling, Wilson, Johnson, McA. Johnson and Hemmitt on a textbook of Rail Metallurgical practice. 448
——Chauvenet. Chemical arithmetic and calculation of furnace charges.. 572
——Clarkson & Dyson. Chemical works, their design, erection and equipment. 504
——Dietz & Malinie. L'Argent et les Metaux de la Mine de Platine.. 322
BOOK REVIEWS: (Continued.)
——Fischer. Chemischtechnologisches Rechnen 447
——Fleissner. Eisenhochofenschlacken.. 504
——Fleming. Electric Wave Telegraphy. 62
——Fulton. Manual of fire assaying.... 189
——Geilenkirchen. Grundzuge des Eisenhüttenwesens 190
——Greenawalt. Hydrometallurgy of copper 826
——Hall & Harbord. Metallurgy of steel. 448
——Handbook for ironfounders..... 706
——Hatfield. Cast iron in the light of recent research 766
——Heyn & Martens. Handbuch der Materialenkunde für den Maschinebau 705
——Hill. Laboratory Guide..... 826
——Hinrichsen & Memmler. Der Kautschuk und Seine Prufung..... 322
——Hull. Industrial depressions..... 706
——Jellinek. Hydrosulfit..... 826
——Journal of the Municipal School of Technology, Manchester 189
——Kaye and Laby on tables of physical and chemical constants and some mathematical functions..... 122
——Knight & Byers. A text book of inorganic chemistry 705
——Kremann. Anwendung physikalischchemischer Theorien auf technische Processe und Fabrikationsmethoden 447
——Lang. Metallurgy 256
——Le Chatelier. Introduction a L'Etude de la Metallurgie..... 766
——Lunge. Sulphuric acid and alkali.... 256
——McFarren. Mining law for the prospector, miner and engineer..... 122
——Malinie & Dietz. L'Argent et les Metaux de la Mine de Platine. 322
——Martens & Heyn Handbuch der Materialenkunde für den Maschinebau 705
——McCullough. Engineering as a vocation 190
——Meade on Portland cement..... 448
——Meade and Price. Analysis of Brass. 826
——Neumann. Lehrbuch der Chemischen Technologie and Metallurgie.... 766
——Osann. Lehrbuch der Eisen und Stahlgiesserei 448
——Parry. Systematic treatment of metalliferous waste. 504
——Partington. Higher mathematics for chemical students. 572
——Pitaval, Elektrochemische Industrie Frankreichs 826
——Pring. Laboratory exercises in physical chemistry 384
——Prost. Cours de Metallurgie des Metaux antres que le Fer..... 705
——Regelsberger. Elektrometallurgie.... 705
——Ricketts. A manual of American mining laws 122
——Robin. Traite de Metallographie.... 706
——Sadtler. Industrial organic chemistry 448
——Sauveur. The metallography of iron and steel 766
——Schmitt. Rand metallurgical practice 826
——Senter. A text book of inorganic chemistry 705
——Schloffer. Galvanostegie 256
——Smith. Electro-analysis 122
——Stoughton. Metallurgy of iron and steel 190
——Technology and industrial efficiency. 189
——Verein Deutscher Eisenhuttenleute, Gemeintfossliche Darstellung des Eisenhuttenwesens 504
Borax Lake. Potash in..... 261
BORON:
——for improving copper castings. Weintraub. (P.) 556
——for making copper and zinc alloys. Rockey and Eldridge..... 697
——Reduction and purification. Weintraub. (P.) 309
——Weintraub 620
Bosworth, Harold O..... 384
Braden Copper Co..... 724
Bradley process for low-grade copper ores. (S.) 178
BRASS:
——Electrolytic deposition. Thompson. 458
——Melting in electric furnace. Clamer and Hering 702
——Hansen 703
——Oxygen in. Turner..... 726
——Tin and lead in..... 226
Brass. (See also Alloys.)
Brick for metallurgical furnaces. McNight and Youngman. (P.)..... 309
Brick. (See also Fire Brick.)
BRIQUETTING:
——copper shavings. Glass. (P.)..... 51
——flue dust. Hubner. (P.)..... 696
—— Vogel 164
——Fuel 463
——Groendal process. Hansell..... 166
——Improved channel furnace of Groendal type. Hamilton. (P.).... 752
——iron borings. Valentine. (P.)..... 751
——Schumacher process. Richards..... 165
—— Vogel 164
BRIQUETTING: (Continued.)
——(See also Agglomeration, Balling, Blast Roasting, Sintering.)
British Association 655, 749
British Columbia. Metallurgy. Jacobs.. 112
British Columbia Copper Co..... 113
Bromatology at Congress.....615, 625, 636
Bronze. (See Alloys.)
Brown Instrument Co.....186, 445, 763
Brown, A. H..... 255
Brownlee, A. G..... 188
Buckets. Elevator. Maguire. (S.)..... 695
Burch, H. Kenyon.....255, 569
Bureau of Mines...65, 258, 503, 544, 678, 724
Bureau of Standards.....342, 390
——Analyzed samples.....260, 763
——Metallography and metallurgy. Burgess 467
Butte & Superior..... 771
Butters, Charles 569
Byproduct Coke Ovens. (See Coke.)

C

CADMIUM coulometer 620
Caetani, Gelasio 121, 187
Calculations. Uniformity and simplicity in electrochemical. Hering..... 285
California Miners' Association..... 563
California. Smelting and agriculture... 261
Callbreath, James F..... 703
Calorimeters 160
Carbon dioxide automatic analyzers..... 121
Calumet & Hecla Co..... 377
Cameron, F. K. Portrait..... 601
Camp Bird 262, 281
Carbon crystallization. Artificial. Howell. 197
Carbon dioxide detecti[illegible]..... 605
Carbon dioxide mete[illegible]...121, 382, 497
Carbon monoxide [illegible]ide nomenclature. La[illegible] 14
CARBIDE OF SILICO
——Dense. Tone. (P.)..... 550
——Temperature of formation. Saunders. 287
——Bancroft, Walker and Miller..... 685
——Norton Co. plant..... 519
——Refractories. Fitzgerald 129
Carbides and nitrogen. Tucker and Yanz 584
Carbon-silicon refractory. Acheson. (P.) 550
Carbon determination in iron and steel. Robinson 295
Carborundum. (See Silicon Carbide.)
Carlyle, E. J.[illegible] 446
Carnotite ores. [illegible]oncentration. Fischer. 356
Carnotite. Va[illegible]n from Fischer.... 469
Carpenter, A[illegible] H..... 504
Carter, T. Lan[illegible] 704
Case hardening. [illegible]bbott & Ammon.... 802
Case hardening of [illegible]pecial steels. Sauveur and Re[illegible]ardt 813
Castings. Steel. Crucible vs. Tropenas converter vs. electric furnace.. 54
Cathode. Rotating. Bennett..... 298
Catlin, Seth Clinton..... 446
Caustic alkalis, alumina, hydrochloric acid and cement from salt, clay and lime. Cowles..... 659
Caustic soda. Action on boiler plates.... 46
Caustic. Electrolytic. (See Sodium Chloride Electrolysis.)
Caven, T. M..... 764
Cell. Dry. Construction and manufacture. Richardson 531
Cells. Dry. Report of Am. Electrochemical Society Committee 361
——Short-circuit current and deterioration. Hambuechen 364
——Melsom. Nat. Phys. Lab..... 365
Cellulose 616, 624 636
Cellulose. Bamboo 609
CEMENT:
——alumina, hydrochloric acid, and caustic alkalis from salt, clay and lime. Cowles 659
——grinding. Sturtevant 380
——Portland. Control of dust. Schmidt. 611
——Portland. Magnesia in..... 612
——Portland. Properties. Reibling and Reyes 612
——Portland. Setting. Cushman..... 611
——Portland. Testing for free lime.... 613
——Setting. Recorder. McKenna..... 82
——Statistics for 1911..... 127
Centrifugal action producing e.m.f. Miller. 297
Centrifugal gaswasher. Feld..... 436
Centrifugal separation of ore slime. Peck. 235
Charcoal iron. Effect of high carbon. Johnson 777
Charges of furnaces. Calculation. Chauvenet 36, 104, 135, 220, 338
Chemical equations. Balancing. Wilson. 94
Chemical Formulae. Bailar..... 262
Chemical industries. American..... 199
Chemical industry of Germany. Achievements and problems. Duisberg. 620
Chemical Process Co..... 182
Chemical processes. Commercial development. Whiting 627
Chemicals, oils and paints. Glossary.. 199
Chemist-analyst 108
Chemists' Club 10, 637
Chilian Mills. Slow-speed. Empson. (S.) 244
Chino Copper Co.....196, 654
Chlorate plant in France..... 716

Chlorides reduced by sodium. Hunter... 623
Chlorine. Electrolytic. (See Sodium Chloride Electrolysis.)
Chlorine-proof ebonite. Wilderman..... 629
Christy, S. B..... 503
Chromium-cobalt alloys. Haynes..... 804
Clam shell filter..... 493
Clark, Kilburn D..... 764
Classification. Hydraulic. Robertson... 793
Classification of ore pulps for concentrating tables. Shepard 218
Classifier. Richards. Pulsator..... 61
Classifier. Shaking. Inclined-screen hydraulic. Skinner..... 343
Classifier and agitator. Fairfield. (P.).. 177
Clay for production of alumina, hydrochloric acid, caustic alkalis and hydraulic cement. Cowles..... 659
Claudet, H. H..... 61
Cleaning gas. Johnson. (P.)..... 555
Clevenger, G. H..... 569
COAL:
——Artificial production. Bergius..... 648
——Coking at low temperatures. Parr and Olin. (S.)..... 755
——Dust as open-hearth fuel. Barbanson and Lepersonne. (P.)..... 485
——Gas. Extraction of ammonium sulphate. Feld. 395
——Gas. Purification with recovery of byproducts. Burkheiser 691
——Low-grade lignite coals. Babcock... 691
——preparation. Ayres 691
——Spontaneous combustion 645
——Strike in England.....241, 302
——Sub-bituminous. Constitution and genesis. Thiessen 691
——Tar colors at Congress.....614, 624
Cobalt-chromium alloys. Haynes..... 804
Cobalt-nickel-silver-arsenic ores. Vacuum furnace treatment. Fink..... 296
Cohesion. Intercrystalline in metals. Rosenhain and Ewen..... 725
Cohesive forces. Electrical energy from. Hering 14
Coke. Neutral. Campbell..... 690
Coke ovens. Beehive..... 645
Coke ovens. Byproduct. Papers by Blauvelt, Andrews, Lucas..... 806
Coke ovens. Byproduct in U. S. Hartman. 521
Coke-oven gas for open-hearth furnaces. (S.) 47
Coking coal at low temperature. Parr and Olin. (S.) 755
Coke. Removal of sulphur. Spurrier. (P.) 50
Colby, Albert Ladd..... 61

Properties
——Pulp control by specific gravity flask.
——Retreating Rand tailings. (S.)
——Sampling and assaying silver ores containing cobalt, nickel and arsenic. Handy.
——Scaling amalgamated plates
——Silver. Bismuth alloys. Refining. Lacey.
——Slime plant Kelly P.
——Slime treatment Young (S.)
——Slimes Filter)
——Slimes, treatment Lawden
——Slime thickener and decanter. Lamb. (P.)
——Slime treatment in Victoria. Nicol. (S.)
——Solubility in nitric acid of gold contained in copper bullion. Keller. (S.)
——Treating gold-bearing clay. (P.)
——Zinc-dust precipitating apparatus. (P.)
——Zinc dust testing. Sharwood. (S.)

Nineteen Hundred and Eleven.

In any valuation of business prospects in this country one fact must be ever kept before the mind's eye. This is that America is a youthful nation with the faults and virtues of youth. Americans are as different from Chinese as if the latter lived in Saturn. They live in the past and worship their ancestors. We live in the future and look for a continuation of our individual spiritual entities after death.

Now the foremost characteristic of youth is the profound major chord of optimism dominating its entire life and the resultant reaction from that attitude for short intervals. It is thus true that in our national life we have periods when fear and doubt challenge the attention. We have seen alternations in our industrial life as in the life of a youth ever since the Constitution was adopted in 1789 and Benjamin Franklin made his now famous remark that the picture over the presiding officer's chair represented "the rising sun, not the setting sun." Summarized briefly, we have seen recently the depression of 1893-6, the boom of 1900-02, the rich man's panic of 1903-04, the flood tide prosperity of 1905-06 and the widespread panic of 1907 with its subsequent period of retrenchment.

Furthermore, we have observed the hysteria of 1907 vanish in eighteen months and the national spirit reverse itself in the time of elation and apparent prosperity from July, 1909, to September, 1910. This was exaggerated in point of fact and there has been manifested a general mental attitude of doubt and perplexity in the past sixteen months, gradually turning into a time such as the present, when confidence and assurance begin to outcrop. In a highly exaggerated form, alienists recognize a similar course of mental events in what they denominate as "alternating insanity." Here, of course, the unintelligence is most pronounced. In the milder neurasthenic cases there are the same phenomena. If we assume the Hegelian theory of a national individual soul which is at least a good working hypothesis we can compare these alternations in business to the alternations that exist in any youthful mind. Now, in sane individuals these alternations are mild. An even and balanced mind discriminates between unreasoning hope and an abiding faith, between hysterical fear and sensible caution. It can be laid down as a fact that our panics have been growing less severe in the past fifty years. We perceive a greater extension of business intelligence throughout the United States and we believe that our industrial organism is animated by the general diffusion of the laws of economics and sound finance. It is a direct and logical deduction to say that these are related and to compare our now less pronounced industrial alternations to those of a heavily dampened pendulum. This is to our way of thinking a salient feature of our modern business life. In short, we are growing older and more sensible

Unquestionably the rise and fall are at any rate less secure. There is a tide in the mental affairs of men which receding leaves bare a few unsightly feats. But always as the Saxon poet says "Bac comes flowende flood aefter ebban."

So much for the general and philosophical argument of the situation. The specific events, we believe, give evidence of a marked agreement between theory and practice. They all seem to point to a general sane expansion and the removal of fear. The most striking event of the past year was, of course, the two decisions of the Supreme Court in the two "Trust" cases. This was most difficult, but was accomplished with judicial dignity, perspicacity, and practical sense. "The rule of reason" simply means that in interpreting any statute common sense takes cognizance of notorious social conditions and that "de minimis lex non curat" is not to be perverted by a meticulous consideration of verbal minutiæ. It means, too, Americans only allow the existence of organizations of labor or of capital provided their actions are governed by intelligence. The application of the Sherman law to labor unions is easy and just. It is of special significance and is directly applicable to the concatenation of events that lead up to the "McNamara case."

This is to our mind the second event in point of importance in the past year. It has brought to the labor unions and their leaders a realizing sense of their own responsibility. They see now that "as they sow, so must they reap." It is certainly to the credit of the American workingmen that their utterances on the outcome of the McNamara case have been most sane and most fair. But it was not to their credit that they paid no attention to evidences of murder till the murderers confessed.

A third important action in the realms of politics and business was the decision of the Interstate Commerce Commission in refusing to allow the railroads to raise their rates. This was hailed generally by the American people as just and reasonable. It shows we are still a government of the people, by the people, and for the people.

Among events more direct in their relation to business are the immense cotton crop and the fall in the price of the staple to a figure that encourages export trade and domestic buying. Though nine-cent cotton is not an unmixed blessing, it is a compensation to the textile industry.

In addition, our present export trade in all manufactured articles has increased to a degree almost comparable to the expansion of 1898-1900. Indeed our export trade for the past year promises to be in excess of two billion dollars. This has given us large credit foreign balances. We have also seen an all-round increased efficiency in our industrial operations due to the wide diffusion of technical knowledge. Labor, too, while it has not "liquidated" in point of nominal wages—perhaps in view of the higher cost of food products it is not right that it should—has "liquidated" in reality because of increased efficiency and decreased refractoriness.

On the other side of the ledger are the poor crops and the political unrest of the Presidential year, the still prevalent idea that life should be made one round of the "so-called pleasures," the machinations of the ever-present demagogue and of the crass materialistic politician. Both of the latter types we must always expect to have with us as irritants, like the mosquitoes and flies in the warm months.

Therefore on striking a balance of the debit and credit of the year industrialwise, it is manifest that 1911 has been a very good one for the youthful nation. The year has taught us the worth of the German near-classic proverb, "Arbeit macht das Leben suss, Faulheit starkt die Glieder." On one side, in the last analysis character and its antecedent hard work are the only thing that counts. On the other side, it is, of course, evident that fat legs do not make character nor is there anything ethical about magnitude.

An American proverb that ought to be classic is "The reason that people who mind their own business succeed is that they have so little competition." This is most pertinent to the American people. At present it is learning the force of the real meaning behind both proverbs. Though a youthful nation we are a thoughtful nation and are increasingly possessing the grace of reason as the years roll by. Business is becoming more sane and more settled. We have not had a bad year in 1911 and there is in sight a probable expansion of business in 1912. It should be expected that this expansion will be likewise more sane and more uniform. Its measure is contingent upon the self-restraint of our people, the size o fthe crops, and upon the release of capital that has been saved in the times of depression.

This release depends largely upon the course of political events. A common-sense President can be neither a reactionary and ultra-conservative nor a shouter for change and still be great—strange as it may appear. The President inspires the prosecuting machinery of the government. He can use this power to alarm or to assure the business world. The President is responsible for the country and a quasi-judicial power must be exercised by his subordinates. But it is quite certain that those who mind their own business cannot be prosecuted for violating the Sherman law and restricting competition.

Concluding this brief review of the past events and of the signs for the future, we can say that barring international complications of a serious nature, the business world should expect a prosperous and happy New Year. A large part will be played in future prosperity by increased efficiency in the metallurgical and chemical industries. To our readers typifying this element in the evolution of this country and of mankind, to all and everyone, this journal extends heartily the compliments of the season.

Copper Metallurgy in 1911.

No very striking developments in the metallurgy of copper have taken place within the past twelve months. Progress has been made along established lines, and such improvements as have been accomplished have, in general, occupied several years in gaining a permanent place. Among these is the general adoption of the basic-lined converter. Although not a new practice, it is only within the past year that there has been a practically complete abandonment of acid-lined converters in favor of those with basic linings. Saving in cost by converting with basic linings has amounted to approximately $1 per ton. A campaign on a single acid lining was rarely of greater duration than a day, with a duty of from 50 to 100 tons of matte; whereas, with the costly magnesite brick lining, 3,000 to 5,000 tons have been treated in a campaign, and the converting cost per ton has been greatly reduced.

Contrary to expectations, the difficulties anticipated in changing the manner of supplying the silica required by the iron of the matte as it became oxidized, proved to be of little importance. While formerly the question of silica supply caused the metallurgist no concern when acid linings were used, because the iron oxide formed would seize the necessary silica from the lining, now with basic linings and silica supplied in loose form, no more concern is felt; for the range of silica to ferrous oxide is so great that fusible slags will form with any of the proportions likely to exist in the converter at any given time. Add to this the fact that converter slags are always resmelted in blast or reverberatory furnaces, and it will be seen that basic converting is very simple and no surprise should be exhibited on seeing successful work being done with basic converters by workmen who, but a few months before, were familiar only with acid practice.

In smelting operations there seems to be no good reason for expecting any marked change in current practice, which has not varied much during the past decade. In this period the giant furnaces were introduced: reverberatories with a hearth area of 116 feet by 19 feet smelting 300 tons of charge a day, with a consumption of as little as 20 per cent coal, and blast furnaces 56 inches by 87 feet at the tuyeres, with a daily capacity of 3,000 tons of charge, using but 8 per cent coke. Such figures force us to the conclusion that there is not much chance for improvement in this direction. In favored localities the application of fuel oil to reverberatory furnaces has been successfully introduced. Efforts aiming at the use of powdered fuel, as in cement practice, have so far met with no success when applied to smelting.

The recent great development of the so-called "porphyries" has attracted much attention to the low-grade copper deposits. With copper present in such small percentages, approximating in many cases but 1.5 per cent, and also very finely disseminated, the question of its beneficiation is really a matter more of ore dressing than of smelting. The great losses during concentration, ranging close to 30 per cent, are the source of much alarm and the cause of much investigation. A study of the subject shows that the losses occur mainly in the very finely divided material, and that the vanners, which are almost exclusively used as fine concentrators, are very poor devices when considered from the standpoint of percentage of saving. Of course, these or similar machines saving sulphides which otherwise would be lost, may be said to be producing a product that deserves to be ranked as "velvet," yet so inefficient are they that attention should be directed to the development of machines which truly merit the name of "slimers."

One large copper company is endeavoring to overcome this slime difficulty by the use of Garfield tables for preliminary dressing, following this with extremely careful classification before final concentration. While this improves the extraction it cannot be said to solve the problem satisfactorily. Two other large companies are attacking the slime problem in another and more logical way, aiming to secure a real slime concentrator. Much promise is given by centrifugal separators, one type of which, operating on material finer than 200-mesh, produces concentrates ranging from 10 per cent to 13 per cent copper with accompanying tailings of less than 0.5 per cent copper, representing a saving of over 83 per cent; this, too, on a rated capacity of 250 tons per day per separator. Active efforts are also being directed toward the recovery of the copper in the tailings of the Lake Superior properties.

We may expect our most important advances in copper treatment along the line of improvement in concentration, or in chemical or electrochemical methods. The latter method of treatment is most promising, especially in view of the fact that electrical power installations are being so generally exploited. Hydroelectrical development in or near many of the mining sections is in rapid progress, and if the resulting power is readily available and cheap, it will have a very important influence in the encouragement of electrometallurgical methods. There are methods of this character, sound in principle, which are only awaiting an opportunity for a demonstration of their merits on a commercial scale and basis. That one or more of the processes recently developed will prove successful seems to be beyond doubt.

As in smelting, so in refining, no striking changes have taken place in the past year. With the exception of most of the Lake Superior copper, all copper is now electrolytically refined. It is interesting to speculate on the future of "Lake" copper, and to wonder how long it will remain a standard; what will be the result of increased depth on the quality; and how soon, because of the presence of a larger percentage of arsenic and other impurities, it will become necessary to electrolytically refine all Lake Superior copper.

A phase of the copper-smelting situation quite as important as the various treatment problems is the attitude of farmers and the United States Department of Justice toward the smelters. In Utah several smelters have been shut down by the courts, some being allowed to operate only under restrictions. In Montana, after winning a suit brought by the farmers to enjoin the operation of the Washoe smelter, and having the United States Circuit Court of Appeals sustain the findings of the Master in Chancery and of the District Judge, the Anaconda Copper Mining Company was threatened with a similar suit brought by the United States Government. Fortunately, after a friendly discussion, it was decided to place the matter in the hands of a commission selected jointly by the government and the company. This agreement is now in effect.

The situation is not so favorable in California, however, and in the near future we may not find an operating smelter in that state. The farmers are very unreasonable, and, flushed with previous victories in debris litigation and over various smelters, seem bent on showing their power. In Shasta county but a single smelter, the Mammoth, is operating, the Balaklala having shut down during the past summer after realizing the futility of attempting to continue under existing conditions.

In Nevada a smelter was threatened with injunction almost as soon as its site was selected, and smelters planned or in course of erection have been warned that injunction suits are certain to follow the blowing-in of furnaces.

Unless friendly agreements are made to submit the question of smoke and fume damage to commissions or to non-partisan boards of arbitration, the operation of copper smelters in many parts of this country will become a practical impossibility.

Gold and Silver During 1911.

The supremacy of the cyanide process in the metallurgy of gold and silver was more firmly established by the events of the past year, so that in considering advances in the treatment of gold and silver ores, it is practically unnecessary to go outside the progress in cyanidation. Chlorination apparently lost ground, for near the close of the year the only remaining important chlorination mill in the United States announced a suspension of operations, at least temporarily. The full significance of the announcement does not appear, but it may mean the final abandonment of chlorination as a competitor of cyanidation.

Along chemical lines the most important item in cyanidation was the announcement of the principles of the Clancy electrochemical process, and the completion and operation of the first mill to adopt the same. In brief, Mr. Clancy's proposal includes the use of cyanide, with an amide such as calcium cyanamide, and an alkaline haloid such as potassium iodide, together with electrolysis of the pulps during extraction. The net effect is the decomposition of the cyanamide into cyanide, and the regeneration of cyanates, sulphocyanides, etc., into available cyanide; while cyanogen iodide is formed and constantly renewed during electrolysis. The main object sought is a cheaper source of more active solvents for the precious metals.

The announcement of the process created a great deal of interest, and resulted in many experiments by metallurgists throughout the country. Opinions as to the feasibility of the process on a large scale were almost as various as the number of experimenters. Each found obstacles of different kind, as all the conditions for successful experimentation were not known. There was also a frank doubt expressed regarding the possible effect of complex secondary reactions at the electrodes, it being felt that the reactions would not proceed with the simplicity outlined by the inventor.

At the close of the year, however, we were furnished with some details of operation of the first plant actually using the Clancy process. It is handling Cripple Creek sulphotelluride ores without preliminary treatment in the way of roasting or concentrating. The other Cripple Creek cyanide mills employ concentration to eliminate the sulphotelluride mineral, only the tailings being treated by cyanide. It is in the direct chemical treatment of this class of ore that the Clancy process is expected to show material improvement. From results obtained to date it is expected that the operating cost will be little more than $1 per ton, including 12 cents per ton for chemicals. The tailings are showing a value of about $1 per ton. The current density employed is about 7 amperes per square foot of anode surface.

An important point emphasized last year was the necessity of considering the phase rule in cyanidation. It is well known that the solvent action of a cyanide solution diminishes as the point of equilibrium between potassium cyanide, potassium-gold cyanide, and undissolved gold is reached. This point having been reached, dissolution of the gold ceases, and the extraction cannot be materially increased even on longer agitation and the addition of fresh cyanide. The most logical conclusion is that the removal of the solution containing potassium-gold cyanide is essential, and that the substitution of a fresh cyanide solution may then materially increase extraction. Hence the advisability of designing plants so that the ore pulp may be treated with successive applications of cyanide solution, the latter being removed from the system as chemical equilibrium is approached or reached.

This leads to the highest development of the counter-current system of cyanidation, with continuous agitation and decantation, in which the richest ore is in contact with the richest cyanide solution, while the ore most nearly impoverished is treated with barren cyanide solution of high solvent power. This idea of continuous treatment is gaining ground rapidly, and, in the minds of many metallurgists, is tending to become standard practice.

Agitators of the central-tube type, in which either air or mechanical agitation is used, have been adapted to continuous systems very successfully. The vital point to be observed is the steady transference of a uniform quantity and quality of pulp from tank to tank, so that classification of sand is avoided. If this condition is not observed, difficulties will be experienced on account of coarse sand accumulating in the tanks, while slime and fine sand alone passes through the system. The only sure way of avoiding classification is to transfer a portion of the pulp overflowing the central lift-tube, using a cutting vane for this purpose.

The Parral agitating tank made its appearance last year as a rival of the now well-known Pachuca tank. Economies are claimed in the items of capacity, cost of treatment, and efficiency of air agitation and extraction. In the construction of the Parral tank there is no definite ratio to be observed between height and diameter, as in the Pachuca. It has four or more air-lifts placed at uniform distances from the center, with discharge pipes arranged so that a swirling movement is imparted to the contents of the tank.

The A-Z agitator is still popular in Australia, but has made no progress in this country.

The treatment of slime is probably the most important mechanical problem in cyanidation, and in this respect filtration shares the importance of agitation. While there is still rivalry between different forms of filters of the same type, the field of usefulness of the different types is becoming pretty well settled. For pulps composed mainly of coarse and finely ground sand, with little colloid matter, the pressure filter is superior, giving thick, permeable cakes. With pulps containing an excess of clayey or colloidal material, it is doubtful if pressures greater than those obtainable by vacuum are of advantage, and vacuum filters are generally used and recommended for this work. A recent investigator has announced that, in his opinion, the thin-cake, continuous vacuum filters are an improvement over the thick-cake, intermittent machines.

For precipitation of gold and silver from cyanide solutions, zinc dust unquestionably is growing in favor, and the later large installations have been of this type. The advantages over the use of zinc shavings are in general a lower original cost of zinc, a lower consumption of zinc, a higher grade of precipitate, a more accurate check on mill recovery, and less chance of loss by theft or fire.

An innovation only recently announced is the use of electrolytic oxygen to counteract the formation and effect of reducing agents in mill cyanide solutions, particularly those in

plants treating sulphides, tellurides, etc. In such plants the cyanide solution loses its dissolving power, even though the cyanide strength of the solution be kept up to standard. If silver predominates, the effect is still more marked. Various oxidizing salts have been used to overcome this difficulty, but have proved inefficient in many cases. A striking example of the efficient use of electrolytic oxygen is given in an article by Mr. Parmelee elsewhere in this issue. The application of this idea is expected to prove of exceptional value in the cyanidation of concentrates.

The Present Status and Prospect in the Metallurgy of Zinc and Lead.

Now that the cyanide-chlorination gold-extraction controversy seems to have been pretty definitely settled in favor of cyanide—at least for the present—the subject sure of most immediate interest and response in any gathering of metallurgical men is the treatment of complex sulphide ores. A study of the patent-office records of the world will show the same activity and interest. Several things seem fairly clear from such a study: First, no universal method has yet been discovered; second, no mechanical method can hope to become universal; third, nothing like a complete study of the situation has ever been published, if made; fourth, many metallurgical proposals and experiments are being made by men evidently unfamiliar with the handling of ores, solutions, fusions or gases in quantity; and fifth, there must be large quantities of these ores awaiting treatment.

Of these five conclusions, probably only the last needs comment. Mr. Ingalls' recent statement that most of this complex ore tonnage exists not in large deposits, but scattered in many small mines, is undoubtedly true, and greatly affects the problem. The successful process ought to be as suitable for use by the small mine as is concentration or cyanide. We once saw a man in Nevada profitably working his mine and mill single-handed. He drilled and broke his own $12 oxidized ore, shattering it as much as possible with the powder. He wheeled it out of his own tunnel, dumped it over his own screen, sending the coarse to the dump and the screenings to eight whisky barrels, where his own cyanide solution worked while he slept. This is of course a most extreme case, but it represents the ideal from the standpoint of the small mine owner.

It seems improbable that any such ideal will ever be within reach of the small producer of complex sulphides. Lead and zinc are cheap, heavy metals, which must be handled in tons, not ounces. They cannot be exchanged at the mint for coin, but must be sold on the metal market in competition with similar metals produced cheaply on a large scale. This means organization and co-operation, at least so far as sales are concerned, and if the history of mining in America teaches any one thing clearly, it is that small mine owners will not organize and co-operate.

The larger metallurgical concerns are spending large sums on this complex ore problem. They are much more likely to succeed than is the isolated inventor or small mine experimenter. Most of the reasons—such as command of capital, technical and business ability, resources in the way of plant, varied ore supply, etc.—are obvious enough, but there are several other reasons not quite so evident. One is what may be called market knowledge. Another is prestige, the weight of a good name and known achievement back of a process. Still another is knowledge and control of proper publicity, with power to get it when needed or to avoid it. A fourth is the elimination of risk. Any metallurgical process installed at a single mine assumes not only its own risk of failure (because of its own defects or weaknesses), but also assumes the mining, financial, and commercial risks of the mine itself, such as failure or change of ore supply, lack of proper capital, poor management, etc. Many a metallurgical experiment has been written down a failure which might have had some measure of success except for these contingent risks.

The larger mining and metallurgical concerns are in a much better position to estimate, minimize and discount these risks than is an individual or a small mine. This does not mean discouragement of individual effort—it means that individual effort is more likely to succeed when properly directed. If it be admitted that the owner of a small deposit of complex ore has slight chances of producing his metals in whisky barrels, or in a small plant of any sort, then his hope should be that a local market may be provided for his ore as mined. In several places, notably Wisconsin and Colorado, such a market exists and is being extended. It cannot be said to be entirely satisfactory, but the business is only some ten years old, and a safe growth must be a slow one.

Correct chemical or metallurgical theory does not insure the success of a process. A metallurgical success is not necessarily a commercial success. Improper location of plant, lack of suitable labor, adverse freight rates, and similar conditions all make for failure, but so also do such factors as lack of market for some one or more by-products, lack of selling organization for commercial products, and the necessity of meeting trade customs. This last item is rather more serious than might be supposed, and needs attention because many zinc-lead processes propose to offer some one or more chemical compounds for sale to various established industries. The amount of time and patience and skill and nerve and salesmanship and money it takes to break through an old-established trade custom, to introduce a new product or even an old one from a new source, or made in a new way, can only be appreciated by men who have tried it, and they are usually too tired and "grouchy" to care to tell about it in print.

It is of course impossible in any note of this length to touch on processes individually. All that can be said is that they are many in number, and some of them are constantly gaining ground, so that each year seems to show a better chance for the ore producer than did the preceding year. The revolutionary method which will do for lead and zinc what Bessemer converting did for copper, or cyanide did for gold, has not yet appeared. Of the possibilities of electrochemical methods we speak in a separate note.

One thing should be done for the benefit of the many workers along this line. The history of the various attempts at handling these ores lies in uncollected fragments scattered through the note-books, periodicals, technical society journals, patent office and court records of the entire world. Some of it has never been put on paper. The actual results obtained, the reasons therefor, and the details of apparatus and manipu-

lation are not to-day accessible to the metallurgical investigator, who is accordingly forced to cover much ground already proved barren. In view of the importance of the problem, the need for an authentic compilation of scattered material is evident. When it is undertaken, we hope that every interested engineer and operator will contribute liberally from his stock of knowledge.

Iron and Steel in 1911.

In a commercial review of the iron trade one must draw a clear distinction between the swings in the actual consumptive requirements of the country and the swings in demand upon the mills for material. As a rule these do not coincide, and the divergences frequently create interesting market history when without them the developments from month to month and from year to year might prove wearisome and the history of the events quite insipid.

As a rule, many of the products of the iron and steel industry are not in form for direct utilization, for ultimate consumption. When they pass outside the iron and steel industry proper, they must, usually, be fabricated before actual consumption or utilization in the daily life of man occurs. The few forms which are susceptible of final application in the form in which they leave the industry—wire nails and wire fence, for instance—generally pass through the hands of jobbers and retailers.

Thus it occurs that as regards a very large tonnage of the industry's product there are two streams, one from the producers to jobbers and manufacturing consumers, and another from these into actual consumption. The intermediary storage reservoir, the stocks in the hands of jobbers and manufacturing consumers, is subject to wide fluctuations of level, and in connection with these fluctuations much interesting market history is made, and, indeed, most disturbance is created.

The actual consumption by man in his ordinary vocations does not vary greatly from year to year, though there is an almost constant increase from year to year, interrupted or retarded only by periods of real and prolonged general industrial depression. The variations in production of such material, however, are wide, due to increases and decreases of these stocks held in intermediate hands. The mills do not carry stocks to any extent.

Two striking exceptions from the class of material just mentioned are to be noted. The railroads buy directly and in a strict sense do not carry stocks. Their consumption, regarded as the wearing out of material, varies but slightly, for the total ton-mileage in freight and passenger-mileage in passenger traffic does not fluctuate widely by any means, nor does the need for replacement of bridges, stations, etc., arise other than gradually. Nevertheless railroad purchases do fluctuate violently from time to time. Another exception to be noted is that of permanent works like office and hotel buildings, toll bridges and the like, in which definite blocks of capital are invested at a single operation, in the expectation of a steady annual return being derived.

The buying, in the case of these two exceptions, is regulated by general financial and business conditions, by the views entertained by railroad men and capitalists as to whether prices of iron and steel are likely to go up or down and whether business conditions will grow better or worse. These influences, however, are largely those which control the action of the jobbers and manufacturing consumers, who allow their stocks to decrease, or who increase them, according to their personal views.

Thus it is that in such a household article, such a durable article, as iron in its various forms we have such wide fluctuations in market conditions. A year ago, in reviewing iron and steel in 1910, we observed that in February pig iron was being produced at the rate of 31,000,000 tons per year, but at the close of the year at the rate of only 20,000,000 tons per year. No such decrease occurred in the actual ultimate consumption or utilization. In the year 1911 we have had nothing like so wide a fluctuation in production, yet we have had fluctuations which were not due to fluctuations in the rate of final consumption. The fluctuations due to changes in sentiment have been more moderate, yet they have been important, and at the close of the year we have a change, due to sentiment, which is particularly noteworthy. However crude the comparison by calendar years may be, a good starting point is furnished for discussion, and we, therefore, set our estimate of pig iron production in 1911, 23,700,000 ± 100,000 gross tons, in comparison with the officially reported outputs of previous years: 1902—17,821,307; 1903—18,009,252; 1904—16,497,033; 1905—22,992,380; 1906—25,307,191; 1907—25,781,361; 1908—15,936,018; 1909—25,795,471; 1910—27,303,567; 1911—23,700,000.

It will be observed that 1911 fell decidedly below four of the five preceding years, 1908 being the exception, with a very small output. The above is the history of production. The history of actual consumption is altogether different, both as to volume and as to the character. In 1905-6-7 there was the ordinary consumption of iron and steel in the ordinary daily life of men, somewhat heavier than formerly because business conditions were better, because population was larger and because iron and steel were being employed in new uses. In addition to this ordinary consumption there was very large consumption through railroads investing fresh capital in improvements and extensions, and through large financial undertakings being carried through, like the erection of office and hotel buildings, bridges, manufacturing plants, etc. Mill deliveries, particularly in 1907, were very slow, and jobbers and manufacturing consumers found it necessary to carry large stocks, or they would be unable to conduct their business properly.

After the panic of October, 1907, the consumption by the investment of distinct blocks of capital came to an almost complete stop, while the intermediaries who carried stocks drew upon them instead of upon mills, finding no difficulty in securing quick delivery of such special descriptions of material as they required. During this year prices were maintained by agreement, which naturally encouraged the policy of reducing stocks to a minimum. In February, 1909, prices were allowed to break, and comparatively low levels were reached. Stocks were at a minimum and as buyers started to replenish them prices were advanced. Such was the temper of the buying trade that advancing prices encouraged, rather than discouraged, the laying in of stocks, and early in 1910 stocks were as much above the normal as in the preceding spring they had been below normal. Before these stocks were reduced to

normal proportions the end of 1910 was reached. In the twelvemonth ending July 31, 1910, production of pig iron was 29,800,000 gross tons, but there is not the least ground for assuming that consumption was nearly as large. The average production of 1909-10 was 26,500,000 tons of pig iron. The year 1909 opened with very light stocks, and the year 1910 closed with normal stocks, and allowing for this fact we may take the average consumption of 1909-10 at between 25,000,000 and 26,000,000 tons, in terms of pig iron, which we find was the average production and consumption in 1906-7.

There was practically no change in total tonnage. There was, however, an important change in the character of the consumption. Railroad buying, and the investment of large blocks of capital in individual enterprises, materially decreased, while on the other hand the ordinary consumption increased.

In the comparison of pig iron production by years, 1911 suffers, but we find the year opened with normal stocks in the hands of intermediaries, but closed with practically no stocks, and allowing for this we find that actual ultimate consumption in 1911 was represented by about 25,000,000 tons of pig iron, the year not differing greatly from other years in the recent past.

The productive capacity at the present time, not the combined estimate of blast furnace managers, but an estimate based upon actual performance when the industry last ran at full capacity, with allowance for the new capacity since created, is about 34,000,000 tons, with steel making and finishing capacity in proportion. Thus we find the industry with about one-third more capacity than it has lately needed, but we find also that while total demand has not increased in five years, the ordinary demand has increased materially, so that if on top of the increased ordinary demand there should come a special flow of capital into large enterprises such as occurred in 1905-6-7, full, or nearly full, employment would be found for the existing capacity.

No such development lies in the immediate prospect. In the closing weeks of 1911 there has come a greatly increased buying movement, attended by much enthusiasm and optimistic expressions by leaders in the trade. This movement is to be studied in the light of what we said at the outset. There has been no important change in the flow of material into actual ultimate consumption; winter is the last time for such a change. Stocks in intermediate hands, however, had reached an extremely low point, and the flow from mills into such stocks is increasing. There is being repeated on a small scale what occurred in 1909 on a large scale, a buying movement after a liquidation in stocks, but there is no reason to suppose it will be carried to the disastrous length of the 1909 movement. Production of pig iron in the past three months has averaged between 24,000,000 and 25,000,000 tons a year, and this rate promises to increase by a few per cent, perhaps ten, in the early part of the new year.

The Non-Ferrous Metal Markets.

The foundations of our modern civilized society are laid on the metallurgical and chemical industries. Indeed, it has been well said that the consumption of sulphuric acid measures the degree of culture and refinement of a country. Strikingly apparent to the man in the street is the fact that we are living in an age of metals. The twentieth century is the golden age, the bronze age, and the iron age rolled into one. The progress of civilization is accordingly interdependent with metallurgical expansion. The metal markets show strength when business waxes, and weakness when business wanes. Last year the general tone of all metal markets was faltering and full of perplexity. This year there is a general air of quiet confidence throughout with, in places, an exaggerated yet in a measure real buoyancy. Each of these phases in our own business corresponds closely with the general business conditions of the United States.

The metals at present are in a strong underlying statistical position. Although statistics are notoriously unreliable, yet viewed and interpreted carefully from a practical standpoint they are a good guide. What constitutes actual consumption is largely a question of definition. When stocks pass from the refiner's hands to the warehouse of the jobber, they are held by some to enter technically into "consumption." But when they pass from the jobber to the retailer, they are surely one step further; as to the bearing of this on the iron and steel industry we speak in the preceding editorial. In the final analysis, metals do not really undergo consumption until they are placed in some useful and permanent form as a copper wire strung on a line and used as an electrical conductor to give a specific instance.

Using this the most rigid definition of consumption, we believe that in the past four years the consumption of all articles and particularly that of metals has been great, far greater than the statistics indicate. Just as in the winter months, even in a country like Ontario covered with snow the water runs through many rivulets to the streams, so in times of depression there are many hidden currents of consumption. To this intangible consumption which has been going on steadily in the past four years, the present strength of the metal markets has been due in large part. Low prices stimulate purchases especially by those who can be called economically wise. At the same time rising prices also stimulate purchasing by the doubtful ones. There has been in the past year much of each of three kinds of buying. We have in mind one central station company that has bought two years' supply of copper wire on a 12-cent copper market. We also have in mind another concern that did not buy until lately when the price for copper increased. For even with the concentration of capital and the unification of management, the laws of economics operate in much the same way that Adam Smith described 150 years ago. To our mind they always will operate, though the diffusion of intelligence both technical and financial tends to preserve a balance and to restrain both excesses of elation and excesses of fear. This is the great contribution of applied science to the twentieth century.

With regard to the particular non-ferrous metal markets but little need be said. All have shown great signs of strength, especially the copper market. For as we said last year, in this age of electricity, there cannot long be too much copper. The new producers of copper have not reached the producing stage as fast as anticipated nor have they produced the quantity expected. These facts coupled with large exports and a good domestic trade have resulted in a strong position for copper.

Spelter has been most uncannily strong. At present its market can be said to be a nominal one. The discoveries at Fryer Hill, Leadville, have resulted in the shipment of large tonnages of carbonate. Improvements in ore dressing such as the Huff electrostatic separator have further increased the tonnage of low-grade zinc ore. This, with the decrease in the number of active retorts due to the exhaustion of the "Iola" gas pool, has made the condition of the smelter quite favorable. For, with a restricted smelting capacity and an increased tonnage of low-grade ore, the smelting companies can do about as they please both in purchases of ore and in sales of metal.

Lead has averaged but little higher in 1911 than in 1910. Its price is so largely controlled by one producer that it fluctuates slowly. The shortage of lead ore is still a problem. Nickel and "monel" are both controlled by one concern, but their production has largely increased. Tin is the only metal not produced to any extent in this country. The price is largely manipulated, but it is only fair to state that it is not produced fast enough for the needs of the world. There is no telling what will happen in the tin market. Silver, of course, is a coin metal and does not fluctuate as do the base metals. At the close of the year its price is slightly higher than a year ago.

It cannot be expected that this increase in the strength can continue for long. In the first place, high prices tend to restrict actual consumption. Next there is a large excess of producing capacity in the metallurgical works of this country, and a continuation of the rise in prices will cause the rehabilitation of abandoned plants and also stimulate the erection of new and improved plants. A pseudo-prosperity or a boom founded on the supposition that our country is ready for a period of inflation would be the worst thing imaginable for the metallurgical industry. But a sane expansion on lines proportionate to the growing needs of modern life is probable. On the other hand, the diminution of doubt and the absence of perplexity is at least gratifying. When the workers are in the foreground and the shouters are in the background, there is little cause for worrying. Such, indeed, is the pleasant condition of the metal business at the opening of 1912.

The Patent Reform Problem Before the American Institute of Chemical Engineers.

The rules which restrict carefully and materially the membership of the American Institute of Chemical Engineers are usually explained on the ground that they are the foundation of the prestige of the Institute. This is so evidently true that another advantage is usually overlooked. It is that this very restriction of membership greatly facilitates intense work on important questions of public policy. The patent reform problem is a case in point. It was the subject of a most interesting discussion at the meeting of the Institute held last week in Washington.

Three formal and very able papers dealt with the subject, the first by United States Commissioner of Patents Moore and the other two by two eminent lawyers, Mr. Edmonds and Mr. Kenyon. A lively discussion followed, in which, among others, Dr. Hill, of the United States Patent Office; Mr. Rogers, president of the Washington Patent Association, and Dr. Backeland, the new president of the Institute, participated. Besides this symposium of papers the members of the Institute had an opportunity to study during one afternoon the details of the working of the Patent Office, and it may not be amiss to refer here first in a few words to the impressions made on the visitors on this occasion.

The work of the United States Patent Office is simply amazing, even to those who are acquainted with our patent system but have no occasion to come in contact with the tremendous and painstaking work involved in all details. One of the striking things is the card index of chemical literature brought together by Dr. Hill and his many assistants, a work of such magnitude that it has taken them many years of diligent work and that it is still consuming their full attention. This card index numbers several millions of cards; it is open free of charge to anybody interested in chemical literature. Anybody engaged in chemical research work, whether the latter be related to patent work or to scientific research, can find there in a much shorter time than anywhere else whatever has been accomplished on any chemical subject. Many a chemist engaged in a search of chemical literature prefers to take the trouble of a trip to Washington to find there quickly all references instead of spending weeks and months running from one library to another. It would be highly desirable if the Public Library of New York had a duplicate of this card index, but the work would involve a rather large outlay of money, which could only be obtained by special donation for that purpose.

The immense increase of the work of the Patent Office due to the ever increasing number of patents has made the old building absolutely obsolete—a regular fire trap where invaluable records may be lost at any time should a fire occur, and the latter risk is imminent on account of the hopelessly overcrowded conditions. It is a pathetic sight to behold the inadequacy of this building and the excessively crowded places in which the examiners and assistant examiners have to perform their work. Yet the United States Patent Office is the only paying department of the country, and has now an accumulated balance to its credit of over seven million dollars. Why not tear down that old and antiquated Greek mausoleum and build a spacious, well ventilated, well lighted, modern fireproof building with part of the seven million dollars and do justice to the inventive genius of the nation and the industries which depend on it?

However, what is more needed than a new building is reform in the patent system—not so much in the patent laws themselves as in the rules of practice of these laws. We venture to express the conviction that the United States patent law is good enough, perhaps better than that of any other nation. But when it comes to settle suits for infringement the whole proceedings become so unnecessarily cumbersome, long drawn, expensive and undecisive that the word *absurd* is really much too mild for it.

This condition of affairs gives an immense advantage to the very rich, whether they are individuals or corporations, as they can draw out a suit indefinitely provided they are willing to stand the expenses attached thereto; it puts the inventor or manufacturer of small means at a hopeless disadvantage. The most needed reforms seem to be the following:

Firstly, a patent court of appeals which can decide definitely all appealed cases, while now the circuit courts often disagree, so that in several cases a patent has been declared valid in one circuit and invalid in another, this leading to hopeless confusion and unsettled decisions.

Secondly, in case of infringement testimony should be taken in open court and before a judge so as to do away with the absurd practice now prevailing that irrelevant testimony can be used indefinitely and without the slightest restraint so as to pad the records and prolong indefinitely the taking of testimony and thus postpone the issue.

Thirdly, the attempt should be made to reduce the unnecessarily large number of appeals in cases of interference, and thus do away with the advantage that a wealthy contestant may have in an interference trial before the patent is allowed making it more burdensome than an infringement suit.

There are many other reforms proposed, but the above mentioned seem to us the principal ones, and unless action is concentrated on the most important ones it is very likely that attention will be scattered again to such a point as to produce no practical result, and that the matter will be further postponed to the detriment of the industries of the nation.

It behooves all scientific and technical organizations to take an active part in this patent reform because conditions have become well-nigh intolerable. The public at large is more interested in this reform than it knows. For after all the public has to pay indirectly but surely the bill of the expensive lawsuits and the uncertainties of patent decisions.

Unfortunately the engineering societies of this country have remained rather torpid and indifferent. There will be no trouble in getting the needed patent reform if those who represent the industries of the country show that they want it The American Institute of Chemical Engineers, the Washington Patent Law Association, the Inventors' Guild, and the American Bar Association are up till now the only organizations which have taken some live interest in the matter. The American Institute of Electrical Engineers is just beginning to do so. Why do the American Chemical Society, the American Electrochemical Society, and the many other engineering societies not take more interest in this vital question?

Electrochemistry and Chemistry in 1911.

While yearly reviews of progress in electrochemistry, written some ten years ago, used to be almost of a sensational character—a new electric-furnace reaction often meant the foundation of a whole new industry or the revolution of an old one—it is different now. Electrochemical processes are no longer in the test-tube stage. The electric-furnace plants of Niagara Falls, the electrolytic copper refineries of New York harbor, the electrolytic caustic and chlorine plants, the aluminium industry—all are now well established old industries working quietly and showing from year to year regular sane and safe commercial advances in output and conquests of the market. Of course, commercial success is not everything in life, but even pure idealists must concede that success is a test of inherent value. From this viewpoint the present quiet and eminently satisfactory position of the established electrochemical industries is clear evidence of the soundness of their foundation.

This fact speaks well for the prospects of electrochemical methods in metallurgy which now attract so much attention. There are many of them of greater or smaller scope in their respective fields. In steel metallurgy the electric furnace is making steady progress. In this country the progress has been somewhat slow—certainly too slow for those who expected a cataclysm of the old order of things—yet the pace has been just what was to be expected from a sane evolution along strictly logical lines. The crucible-steel makers continue to install electric furnaces for high-class steels. At the close of the year the first electric furnace has started operation in this country in foundry practice—especially for automobile castings. But with respect to the biggest problem—the combination of Bessemer converter and electric furnace for the manufacture of steel for rails, etc.—commercial finality has not yet been reached, though steady technical progress has been made, especially in the baking of the very large electrodes required for the large furnaces.

In gold metallurgy there are electrolytic amalgamation, still in the process of evolution, and the Clancy process combining the use of calcium cyanamide and electrolysis as novel features and about which the report reaches us while going to press that the first commercial installation at the Ajax Mine in Victor, Colo., is a decided success. How manifold the methods of electrochemistry are, however, is best seen in connection with the complex zinc-lead sulphide problem. For its solution three essentially different processes are being proposed and are awaiting the commercial test in the near future. Firstly there are the different electric-furnace processes, of which at least three can no longer be said to be in "the infancy of the experimental stage." Secondly, dry chlorination along lines formerly followed by Swinburne and Ashcroft, to be tested in two new plants in Colorado (Malm process) and in Montana (Baker-Burwell process). Thirdly, at San Francisco a plant is going up to test the Reed-Hering process embodying electrolysis of sulphate solution with recovery of sulphuric acid. A more detailed discussion of this whole very interesting and complex situation must be reserved for a later issue.

What was said above about the quiet and eminently satisfactory working of the electrochemical industries may be said of the chemical industries in general in this country. However, there was one glorious main event of the past year, a milestone in the history of chemistry in America—the opening of the new Chemists' Club building in New York. It was wonderful to conceive the idea of a Chemists' Building as a monument representative of the united democracy of American chemists. It was more wonderful to realize this idea without outside help through the combined efforts of American chemists. But the most wonderful miracle is the outcome of the crucial commercial test of the first year—the fact that the Chemists' Building Company made both ends meet and did even better. If anybody has to refute again the still too prevalent idea that idealists are necessarily poor business men, the Chemists' building is classical evidence.

This augurs well for the success of the big event of the coming year—the first International Congress of Applied Chemistry to be held in America. It must be made, and will be made, a success worthy of American chemistry.

Washington Meeting of the American Institute of Chemical Engineers.

The fourth annual meeting of the American Institute of Chemical Engineers was held from Dec. 20 to 23 in Washington, D. C., in accordance with the program given in full in our last issue.

Dr. Leo H. Baekeland, of Yonkers, N. Y., was unanimously elected president for this year, succeeding Dr. Frerichs, of St. Louis.

Several very interesting papers were presented. The most important feature of the professional sessions was a symposium on Friday, Dec. 22, on the needs of the reform of our patent system. United States Commissioner of Patents E. B. Moore opened the subject by an interesting paper, followed by two able and suggestive addresses by Mr. Walter D. Edmonds and Mr. R. N. Kenyon. A very active discussion followed in which Dr. Hill, of the United States Patent Office; Mr. Rogers, president of the Washington Patent Association; Dr. Baekeland and many other members took part.

L. H. BAEKELAND, PRESIDENT AMERICAN INSTITUTE OF CHEMICAL ENGINEERS.

The afternoon of the same day was devoted to a visit to President Taft. Then followed a visit to the Patent Office. Of other excursions that to the Indian Head Proving Grounds proved particularly interesting, occupying the greater part of Thursday. As permission to visit the Proving Grounds is difficult to obtain, and societies have thus far been refused admission, it was an exceptional privilege extended to the Institute.

The banquet at the New Willard was a very entertaining event and well attended. Dr. Chas. F. McKenna was a brilliant toastmaster, introducing successively retiring president Dr. Frerichs and President-elect Dr. Baekeland. Further speeches were made by United States Patent Commissioner Moore, Rear Admiral Twining, Colonel Dunn, Dr. Stratton, director of the Bureau of Standards, and Dr. H. W. Wiley. Dr. Hillebrand, of the Bureau of Standards, was also one of the invited guests.

On the whole the meeting was a really fine success. A full report of the papers presented at the meeting is reserved for our next issue.

Program of London Meeting of the Institute of Metals

The London meeting of the Institute of Metals will be held at the Institution of Mechanical Engineers, Storey's Gate, Westminster, S. W., on Tuesday, Jan. 16 and Wednesday, Jan. 17, 1912.

The meeting will commence on Tuesday afternoon when the president-designate (Prof. W. Gowland, F. R. S.) will deliver his inaugural address on the subject of "Copper and Its Alloys in Early Times." In the evening of the same day the annual dinner of the Institute will be held.

The whole of Wednesday, Jan. 17, will, if necessary, be devoted to the reading and discussion of a number of interesting papers, among which may be mentioned the following: "Properties of certain copper alloys at high temperatures," by G. D. Bengough; "Further experiments on the inversion at 470° C. in copper-zinc alloys," by Prof. H. C. H. Carpenter; "The influence of oxygen on copper containing arsenic or antimony," by R. H. Greaves; "The nomenclature of alloys," by Dr. W. Rosenhain; "Poisoned brass and its behavior when heated in vacuo," by Prof. T. Turner, and a paper by Dr. Carl Benedicks, of the University of Stockholm, dealing with some novel experiments on a zinc-antimony alloy. The latter paper, the second to be contributed by a foreign member of the Institute in the past three months, will be unique in the literature of British learned societies, as it will contain illustrations in color reproduced by autochrome (natural color) photography. This is a novelty also in this country.

Mr. G. Shaw Scott is the secretary of the Institute of Metals. The offices of the secretary are at the Caxton House, Westminster, S. W., London.

Chemists' Club.

At the yearly election, held at the Chemists' Club in New York City on Dec. 12, the following officers were elected:

Dr. Morris Loeb, president, Mr. Otto P. Amend and Dr. George D. Rosengarten, vice-presidents; Dr. John E. Teeple, secretary; Mr. William James Evans, treasurer.

The three club laboratories, named in honor of Wolcott Gibbs, Robert Bunsen and August W. Hofmann, are now as completely equipped with distributing mains as those of any college; the vacuum and compressed-air plants have recently been installed. These laboratories are equipped with all the necessary fixtures for work. Apparatus is not supplied, but arrangements for the latter can be made on very short notice without leaving the building. These laboratories can be engaged for periods varying from one week to three weeks.

MORRIS LOEB, PRESIDENT CHEMISTS' CLUB.

The Unveiling of the Wolcott Gibbs Bust at the Chemists' Club.

Of the many memorable events which have already taken place in the new stately building of the Chemists' Club in New York City, none has been more pleasingly touching than the unveiling of the bust of the late Professor Wolcott Gibbs on the evening of Nov. 25.

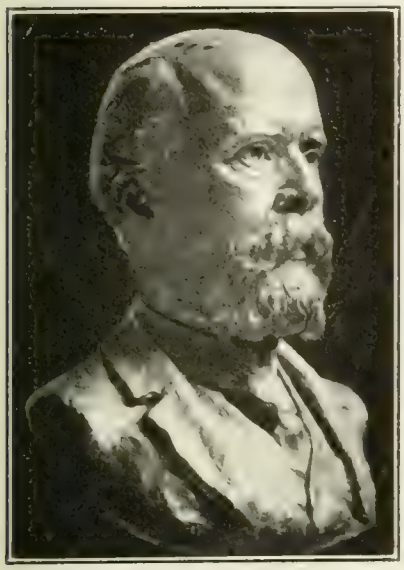
The club members and their guests, including a large number of ladies, assembled in Rumford Hall at 8:30 under the presidency of Dr. Russell W. Moore.

Mr. Alfred W. Gibbs, on behalf of the donors—nephews and nieces of Professor Gibbs—made a short address in presenting the life-size bronze bust, which is the work of the well-known sculptor, Mr. Ernest Wise Keyser.

President Moore in a few aptly chosen words accepted the bust on behalf of the Chemists' Club, whereupon Dr. Charles E. Munroe in an eloquent address (printed in full in *Science*

of Dec. 22, 1911) reviewed in detail the life of Gibbs, his characteristics and his work as a teacher. He emphasized the fact that Gibbs was the founder of the U. S. Sanitary Commission, the first scientific organization of its kind, and out of which the Red Cross movement developed. Gibbs was also one of the founders of the Union League Club and of the Century Association, the former the great patriotic and the latter the important scientific organization of New York.

Wolcott Gibbs' scientific work was analyzed in extenso and the importance of his work on the complex acids and complex bases was clearly brought before the audience. It was remarked that the work of Gibbs and Geuth, on the ammonia-cobalt bases, published by the Smithsonian Institution, was a classic in this complex field of inorganic chemistry.



BUST OF WOLCOTT GIBBS AT THE CHEMISTS' CLUB IN NEW YORK.

Dr. Morris Loeb, in moving a vote of thanks to the family for their generous donation of the bust, and to Dr. Monroe for his brilliant address, read a letter from Prof. Charles Loring Jackson, the oldest living colleague of Professor Gibbs in the chemical department of Harvard University.

Prof. Charles Baskerville, of the College of the City of New York, in seconding the vote of thanks, called attention to the fact that New York can with pride point to the time when Gibbs was professor of chemistry at the Free Academy, now the College of the City of New York, where he was followed by Ogden Doremus.

These exercises were followed by a musical entertainment by a triple quartet from the Columbia University Glee Club—a fitting climax to the dignified and edifying memorial, since Columbia claims Dr. Gibbs as an alumnus.

Then followed some most excellent instrumental music by the "Chemists' Club's Own" trio from the Music School Settlement.

The Chemists' Club may well be proud of this evening, which will long be remembered by all who had the privilege of attending the simple and beautiful exercises.

The Western Metallurgical Field.

Cyaniding Base Ores and Concentrates.

Elsewhere in this issue are given some details on cyaniding in Clear Creek county, Colorado. Reference is made to certain former experiments made in this general district, including Gilpin county, and of the technical success of the same. In this connection the expression of Mr. M. D. Draper, who made the experiments referred to, will be of interest. Mr. Draper's remarks appeared in the Colorado School of Mines *Magazine*.

"Together with several associates, I made a large number of cyanide experiments on the ores of Gilpin county about two years ago, the various tests and experiments covering a period of about one year. It was found that there was no particular difficulty in the cyanidation of the ores; and crude concentrates containing 2 per cent copper and only 10 to 12 per cent silica could be cyanided direct without undue cyanide consumption and with a high extraction of values. In fact the average extraction in a series of sixteen parallel tests, after the proper conditions were ascertained, was found to be 87 per cent. Another point of considerable interest was that the average extraction of several Gilpin county custom milling plants was found to be good, considerably better than has generally been supposed and, in brief, probably in excess of 70 per cent. Notwithstanding this fact, the shipper seldom receives a net profit of more than 50 per cent of the gross value of his ore, and the difference has been found to be due to the freight and smelting charges on the concentrates.

"There is no doubt whatever in my mind, that the establishment of a central milling plant in Gilpin county, with a treatment charge of $2 per ton, would result in unparalleled activity in this pioneer gold district. This plant would use the ordinary present methods of amalgamation followed by concentration, but would differ in cyaniding not only the tailings but the concentrates as well. The present situation, speaking of Gilpin county as a whole, is that the shipper is unable to work at a profit if the grade of the ore is under $6 per ton. In many cases this statement is equally true as to a head value of $7 per ton. A treatment charge of $2 per ton would insure a 300-ton cyanide plant a handsome profit, and the shipper would receive some net return from an ore running as low as $3 per ton, though this figure would not allow for mining cost.

Amalgamated Copper Company and Porphyry Properties.

The decision of the Amalgamated Copper Company to engage in the operation of what are commonly termed the porphyry copper mines, has a wide significance when viewed from several angles. It is Amalgamated's first venture in a field which has hitherto been considered unattractive to them. But the apparent success of other similar ventures, and the possibility of materially adding to the quantity of copper refined and sold by the Amalgamated interests, has probably put the matter in a new light, and has made a consolidation of properties near Miami, Ariz., seem very attractive.

The purchase of the Live Oak by Mr. John D. Ryan consummated a deal which the Miami Copper Company had endeavored to effect, but without success. With the Live Oak in his control and the Inspiration in friendly hands, it appears that negotiations are now pending for the purchase of the Miami, or at least for the consolidation of all three properties into a gigantic copper company under Amalgamated direction. The Miami already has a large mill in operation, and a plant for the Inspiration has been under consideration. It is estimated that with all three properties producing, Amalgamated could add 75,000,000 pounds of copper annually to its already premier production in the copper world.

Another point of view is that the merger would be of benefit to the Raritan Copper refinery, which is owned by the International Smelting & Refining Company, an Amalgamated concern. The addition of 75,000,000 pounds of copper annually to be refined at this plant is a considerable item, and would be a welcome source of income for the International company which has been spending immense sums for construction during the past two or three years.

It is pointed out that conditions for a merger of the Miami, Inspiration and Live Oak properties are most favorable. They are contiguous and have a large tonnage of ore developed which will average about 2 per cent copper. The exploration work on the Live Oak and Inspiration is supposed to have demonstrated a life of twenty-five years at an annual production of 50,000,000 to 75,000,000 pounds of copper per year. When the Inspiration mill was originally talked of, it was calculated that it would produce about 50,000,000 lb. annually. No statement has yet been issued indicating the probable terms of a consolidation, but a merger appears imminent.

The Search for Potash.

The fact that the imports of potash salts into the United States in the calendar year 1911 will have a value of about $15,000,000, is stimulating both government and private enter-

prise in searching our country for possible sources of potash. The matter is of such importance that the government has appropriated $20,000 to enable the U. S. Geological Survey to make a systematic search, cooperating with the Bureau of Soils which has an appropriation of $12,500. At present this money is being expended principally in drilling in favorable locations, notably in the beds of the prehistoric Lakes Bonneville and Lahontan in Nevada. One well known as the Timber Lake Well is to be pushed to a depth of 1000 feet in an effort to locate beds of potash salts. This well is in the bed of Lake Lahontan, as that lake is known never to have overflowed.

Another source of potash which is being investigated is the brines and bitterns from salt works. Many samples of these waste liquors have been collected and are being analyzed, with the result that some of them are showing considerable percentages of potash salts. One natural highly concentrated bittern has been investigated which shows the presence of potassium chloride associated with lime and magnesia, the separation of which offers a nice problem in chemical technology.

More recently, however, workable deposits of alunite have been discovered, and private interests are investigating their treatment. Alunite is a hydrated sulphate of aluminium and potassium containing 38.6 per cent SO_3, 37 per cent Al_2O_3, 11.4 per cent K_2O and 13 per cent H_2O. On heating, this mineral gives up its water and the sulphuric acid, which is combined with alumina, leaving a residue which is 55.6 per cent of the original mass, and of which one-third is soluble potassium sulphate and two-thirds insoluble aluminum oxide. This mineral offers also a possible source of aluminium.

A large deposit of alunite has been discovered near Marysvale, Utah, a portion of which is said to have passed into the hands of the Armours, who are taking out a 100-ton test lot. The mineral is pink in color and has been locally known as pink spar. The deposit has been located in former years as a possible source of metallic value in gold and silver, but no analyses were made and its true value was not known until recently. This is but another example of the advisability of analyzing minerals which are found in abundance in certain places.

Copper Smelter Construction.

On December 2, 1911, the first train load of copper ore from the Nevada Douglas mines was delivered to the new Mason Valley smelter, Thompson, Nev. Although the smelter is not in commission, the receipt of ore points to early operation, and to the increase of copper production in Nevada. The copper mines in the Mason district are the only ones of prominence among those which have been developed in the past few years, in which the ore occurs in vein formation as distinguished from the disseminated deposits of the porphyry mines. The smelter is reported to be one of the best planned and constructed plants in the West.

The Hayden, Ariz., smelter of the American Smelting & Refining Company, which is to treat the concentrates of the Ray Consolidated Copper Company, is being pushed to completion as rapidly as possible. The original site of the plant, on which the Ray company had begun construction, has been abandoned, and new work commenced at another point. This will delay completion somewhat, but it is hoped to have the plant ready for the receipt of Ray concentrates by the stipulated time, April 1, 1912. The power plant and furnaces are being designed for the use of oil as fuel. Two reverberatory furnaces are being built for the immediate treatment of the Ray ore, and no plans are as yet made for the handling of custom ore.

Company Reports.

The third annual report of Stratton's Independence, Ltd., gives some interesting data on the work of the company's mill at Victor, Colo., where the old mine dump and some low-grade mine ore is treated by concentration and bromocyanide. In the fiscal year, July, 1910, to June, 1911, the tonnage treated was brought up to the capacity figure of 10,000 tons per month, having averaged slightly more than that amount in March, April, May and June, 1911. The ore milled during the fiscal year under consideration averaged in gold content, 0.157 oz. gold per ton, which, for the gross tonnage of 109,800 tons milled, gives a total of 17,288.96 oz. gold.

There was recovered in concentrate.... 7,546.80 oz. or 43.65%
There was recovered in bullion..... 4,814.80 oz. or 27.85%

Total recovery .....12,361.60 oz. or 71.50%

The costs of operation in the last three months of the fiscal year, in which the mill reached its estimated capacity of 10,000 tons per month, were as follows:

Milling cost	$1.2390 per ton
Mining cost (dump)	.0891 per ton
Total	$1.3281 per ton

These figures for recovery and cost are remarkably in accord with the estimates of Mr. Philip Argall, manager, made in 1907 on the completion of his tests of the dump ore. At that time he estimated that, on a monthly tonnage of 10,000 tons, an extraction of 70 per cent might be obtained at a total cost of $1.52 per ton treated. Of this total cost he estimated $1.24 per ton for milling and $0.10 for mining. The report states that it is expected to reduce the total costs by 7 cents per ton during the current fiscal year. The working profits from mine and mill have slightly exceeded the estimate of $10,000 per month, and although the mine has not shown any permanent improvement during the year, it is thought that with the mill running at full capacity a profit of $10,000 per month can be continued.

The Goldfield Consolidated Mines Co., Nevada, treated the largest tonnage in the history of the company in the month of October, 1911. The ore production amounted to 30,626 tons, of an average value of $28.09 per ton. This was milled with an average extraction of $26.77 per ton, or 95.31 per cent. The total net profit realized was $616,141.87, or $20.12 per ton. The distribution of the cost, $6.80 per ton, was, as follows:

Mining		
Development	$0.83	
Stoping	2.04	$2.87
Transportation		.08
Milling		1.96
Marketing		.74
General expenses		.38
Bullion tax		.31
Construction		.46
Total cost of operation		$6.80
Miscellaneous earnings		.15
Net cost per ton		$6.65

The construction of the concentrate residues treatment plant is progressing satisfactorily.

Non-Ferrous Metal Market.

The closing month of 1911 witnessed activities in the metal market which gave a more optimistic outlook for the future of some of the non-ferrous metals. Copper and spelter reached a high point, and there was more active speculation, which, however, was based on a feeling that higher quotations are likely to prevail for some time. The quotations on tin fluctuated somewhat, but there was a decided shortage of spot tin, and premiums were demanded. Lead shared the general rise in price.

Copper.—The most important advance which has occurred for a year took place in this market during December. Most of the purchases were for export, but a large volume of domestic business was reported. The last quotations available are 13½ to 13¾ cents for Lake, and 13.45 to 13.50 cents for electrolytic.

Tin.—Early in the month the price was as high as 45 cents, with little business transacted, but later the price dropped to 43.75 cents for December tin, New York. Sales were mostly for future delivery, and little business was done in spot metal.

Lead.—Since our last report the price of lead has been advanced, and the latest quotations have remained unchanged for some days at 4.45 cents, New York, and 4.30 to 4.35 cents, St. Louis.

Spelter.—December deliveries of this metal were made at advanced prices, and as high as 6.75 cents was reported paid, although the highest quotations were nominal. Later, prices fell off, and the last quotations are still nominal, with little business transacted. The market has apparently settled around the following quotations: New York, 6.15 to 6.27½ cents; St. Louis, 6 to 6.12½ cents.

Other Metals.—The aluminium market has been a little more active, with prices slightly higher in New York, viz., 18¾ to 19 cents. Sales of antimony have been larger and the market is firmer. Prices range from 6⅝ to 7¾ cents for various brands. Prices for quicksilver are lower; $44 per flask of 75 lb. at New York, and $43.50 at San Francisco.

The Iron and Steel Market.

December proved to be even a better month in the iron and steel trade than was foreshadowed in our review of a month ago, when it was observed that November opened with gloom universal and closed with sentiment uniformly optimistic. December saw a definite and marked improvement in buying and a slight advance in prices, while it was made certain that production would be increased at the beginning of the new year.

Following the fairly heavy contracting for finished steel products in November there was very heavy contracting in December, and at the same time orders and specifications for early delivery became much heavier. The effect of increased specifying was cumulative, as had been expected in case the start should be made, for all buyers, whether jobbers or manufacturing consumers, had allowed their stocks to drop almost to nothing, and were depending for the ordinary conduct of their business upon the quick shipments which the mills could make upon new specifications. As soon as the mills fell a trifle behind it became necessary for buyers to place additional specifications, to order in advance of requirements, and as such business piled up in mill books, the period of delivery fell farther behind, inducing additional specifying. Thus, from being able to make shipment of many products in from two days to a week in the early part of November, the mills close the year with actual specifications involving from two to six weeks' steady run, while in some cases it is believed that with only a moderate amount of fresh tonnage from week to week full operations can be maintained for from four to six months.

A curious feature of the reaction in prices was that the lowest prices in the entire movement were as a rule found late in November, so that the slight advances which have occurred are the more impressive by comparison. Late in November shading in merchant pipe became fairly general, and the situation was recognized by the National Tube Company issuing a new list under date of December 1, reducing butt weld pipe by one point, or about $2 a ton, and lap weld by two points, or about $4 a ton. At the same time wire prices declined, to a basis of $1.50 for nails.

The advance started with an announcement on November 29 by the Republic Iron & Steel Company that its prices on bars were advanced to 1.10 cents for prompt delivery and 1.15 cents on contracts for first quarter and half, these prices being $1 above the existing market. Other bar manufacturers at once concurred. On December 11 the American Steel & Wire Company announced an advance of $1 a ton in wire products, making nails $1.55, and the independents immediately followed. Next day the American Sheet & Tin Plate Company informally advanced its prices on sheets to minima of 1.90 cents for 28-gage black, 2.90 cents for 28-gage galvanized and 1.40 cents for 10-gage blue annealed. On 28-gage these were advances of $3 a ton from the lowest price done on prompt delivery, and $2 a ton from the lowest done on contracts for the first quarter or half of the new year. The sheet market stiffened at once, although it required some time before prices of 1.85 cents on black and 2.85 cents on galvanized disappeared entirely. At about this time plates and shapes definitely advanced to a minimum of 1.15 cents, the market having previously stiffened by concessions from the open quotation of 1.10 cents disappearing. Bars later advanced to this level, and a few mills advanced their regular asking price on plates and shapes to 1.20 cents.

Making comparison with the lowest prices that were done on particularly attractive orders, the average advance on the whole list of finished steel products outside of rails has been about $1.50 per ton, while the advance in openly quoted prices is fully $1 per ton.

Normally December is a dull month, and phenomenon of activity was probably due to the extremely low prices ruling, with the encouragement furnished by the large car orders recently placed, indicating that railroads, usually slow to buy in a low market, were ready to take advantage of bargain prices.

The net declines in steel products from January 1, 1911, to the low point at the close of November were as follows: Bars, 1.40 cents to 1.05 cents, $7 per ton; plates and shapes, 1.40 cents to 1.10 cents, $6 per ton; merchant pipe, 79 per cent off to 81 per cent off (on ¾ to 1½ in.), $4 per ton; wire products, from $1.70 to $1.50 for nails (advances in the early months to $1.80), $4 per ton; sheets, from 2.20 cents to 1.75 cents occasionally done and 1.80 cents freely done, $8 to $9 per ton; tin plates, from $3.60 to $3.30 on large and $3.40 on small lots, $4 to $6 per ton (with a $3.70 market ruling from February to August) and billets from $23 to $18.50, $4.50 per ton.

Pig iron declined an average of about a dollar a ton during the year.

Pig Iron.

The Youngstown Sheet & Tube Company bought 25,000 tons of Bessemer iron for January and February delivery from the Ohio Iron & Steel Company, at the regular price of $14.25, furnace, other small sales of Bessemer being made at the same figure. The Jones & Laughlin Steel Company bought about 30,000 tons of basic iron for early delivery to its Aliquippa plant, intending to start the steel department, never before operated, without starting the blast furnaces. There are four 250-ton Talbot furnaces. This iron is understood to have gone at special prices, averaging about $12.10. A few sales were made in the month at $12.25 and $12.30, quotations advancing late in the month. In late November and early December a moderately heavy buying movement occurred in Southern iron, chiefly at $9.50 and $9.75, Birmingham, the market later firming up to $10 asked for extended delivery, but occasional lots for prompt shipment being available at $9.75. In New England territory there was fairly heavy buying, at the expense of prices. Prices stand quotable as follows: Delivered Philadelphia, $14.75 to $15 for No. 2 X; f. o. b. Birmingham, $9.75 for prompt and $10 for forward delivery, No. 2 foundry; f. o. b. valley furnaces (90 cents higher delivered Pittsburgh), Bessemer, $14.25; basic, $12.50; No. 2 foundry, $13; forge, $12.50; malleable, $12.75 to $13.

Steel.

Early in December there was heavy covering of both billets and sheet bars, consumers who had previously bought for a month at a time taking December and January deliveries, and in some cases later deliveries also. For the earliest deliveries billets went as low as $18.10 to $18.50 and sheet bars at $19, f. o. b. maker's mill. As buying progressed prices advanced,

and the market closed the month at $19.50 to $20 for billets and $20.50 to $21 for sheet bars, f. o. b. Pittsburgh.

Finished Material.

The year closes with the following prices firmly maintained, f. o. b. Pittsburgh unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill except Colorado.

Plates, tank quality, 1.15 cents to 1.20 cents.

Shapes, 1.15 cents to 1.20 cents. Steel bars, base, 1.15 cents.

Iron bars, 1.25 cents, Pittsburgh; 1.25 cents, Philadelphia; 1.15 cents to 1.20 cents, Chicago.

Wire nails, base, $1.55; plain wire, 1.35 cents, base.

Black sheets, 28-gage, 1.90 cents; galvanized, 2.90 cents; blue annealed, 10-gage, 1.40 cents.

Perkin Medal Award to Herman Frasch.

At the meeting of the Perkin Medal Committee (consisting of representatives of the Society of Chemical Industry, the American Chemical Society and the American Electrochemical Society), held on December 15 at the Chemists' Club in New York, the Perkin medal for 1912 was unanimously awarded to Mr. Herman Frasch for his chemical engineering work in the sulphur and oil refining industries.

The formal presentation of the Perkin medal to Mr. Frasch will take place on January 19 at the regular meeting of the New York section of the Society of Chemical Industry.

CORRESPONDENCE.

Carbon Monoxide and Dioxide.

To the Editor of Metallurgical and Chemical Engineering.

Sir:—I note with interest a communication from Mr. Carl Hering in the December issue of your journal regarding the nomenclature in use at the present time to some extent for defining CO and CO_2.

I want to reiterate what Mr. Hering says in this respect and would recommend that the two gases be specifically designated by the names Carbon Monoxide and Carbon Dioxide. This would leave absolutely no room for doubt or misunderstanding.

I have run across the names lately in several cases when the CO has been termed carbonic oxide, and the CO_2 called carbonic acid much to my disgust and discomfort. This has been in cases of gas analyses which I had occasion to compare with analyses made at the present date, particularly in reference to wood gas, where the content of CO is always rather in evidence. The use of the names carbonic acid and carbonic oxide has caused me a great deal of useless hesitation and figuring, and I suppose my case is not alone in this respect.

I hope that this matter will have the attention of the chemists of the country, to be arranged to better advantage.

Memphis, Tenn. James C. Lawrence.

The Position of the Induction Furnace.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—Referring to Mr. T. D. Robertson's article in your November issue on "The Grönwall Steel Refining Furnace," I wish to comment on his remarks on the induction furnace. He says that "it would appear that the induction furnaces are on a decline." Further on he makes the statement that Messrs. Grönwall, Linblad, and Stalhane "having originally worked with various types of induction furnaces without great success, decided to design an arc furnace."

Even if Messrs. Grönwall, Linblad, and Stalhane have not aided the induction furnace for steel melting and refining, it is hardly proven that induction furnaces are on the decline, except perhaps in Mr. Robertson's opinion.

That the genius of practical, electrical steel men does not always run in the same direction is evident from Messrs. Grönwall, Linblad, and Stalhane's self-confessed failure to produce a successful induction furnace for steel melting and refining; whereas Rodenhauser produced a successful melting and refining induction furnace after many years experience with Kjellin induction furnaces. The Röchling-Rodenhauser electric induction furnace was only commercially built about four years ago, yet to-day there are seventeen built and three building, all of commercial size. This is only one type.

The Kjellin type has produced twelve or more commercial size furnaces and as many more of smaller sizes. There are still other types of induction furnaces.

The writer saw nine different R. & R. and other electric furnaces this summer. One of the R. & R. furnaces is of 10 tons capacity and at the time was turning out tool steel in 10-ton lots, by refining basic bessemer metal with phosphorus 0.08 and sulphur 0.09 and getting the P and S down to 0.008 and sometimes to traces, at the same time achieving a high degree of deoxidation. This refining was accomplished with from 200 to 250 kw-hours to the ton, with a total cost of $4 to $5 for 2204 lb. over the cost of the Bessemer metal. These R. & R. furnaces have been known to melt cold stock with 580 kw-hours to the ton, showing a combined electrical and thermal efficiency of 85 per cent without a residue of hot metal in the furnace.

Surely this is not a decline. The decline is tilted the other way.

C. H. Vom Baur

Electric Energy from Cohesive Forces.

To the Editor of Metallurgical and Chemical Engineering:

Sir: In some recent electrolytic tests in which the metal was dissolved from solid anodes and deposited on the cathode in a loose, finely divided form, the writer noticed that the voltage required was considerably greater than what it was thought it ought to be, because when as much metal is dissolved as is deposited the voltage required for chemical purposes is zero, leaving only that required to overcome the resistances, which should be small.

Its rather large value in this test therefore suggested that it might be due to the fact that the metal was being finely subdivided during the process of electrolysis; this comminution must consume some energy, as the forces of cohesion of the molecules must have been overcome by some larger force, and apparently the only way in which the equivalent of that force can manifest itself in the circuit, if it originates there, is by a counter emf, as it does in the case of an electric motor. Hence the energy of these cohesive forces might in that case be measured electrically.

If this argument is correct, it might follow conversely that if the anode were made of finely divided metal, say a precipitated metal, and the cathode deposit were in a dense form, like ordinary metal, a direct emf would be formed. Hence such an electrolytic cell when short-circuited might possibly generate its own current, if the process is reversible. If so, it would be a case of producing electric energy by the cohesive forces of matter.

The writer did not have the time or facilities to make further investigations. The above should, therefore, be considered merely as a suggestion to those who may have the facilities, time and interest to make the researches.

It recalls another case suggested by the writer many years ago, namely, that when metal is carried from the anode to the cathode between two horizontal plates it should require a less voltage when the anode is the upper one than when it is the lower one, and the difference should correspond to twice the energy required to raise the weight of metal deposited through the distance between the plates. It might also be possible that such a cell, short-circuited, would produce a current. An alternating current passed through such a cell should show a slight direct-current component.

Philadelphia, Pa. Carl Hering.

The Japan Excursion of the American Institute of Mining Engineers

By Jos. W. RICHARDS, Vice-President of the Institute.

The American Institute of Mining Engineers has added one more to the list of its famous and most successful excursions. Of more than local significance, this last pilgrimage has taken on a distinctly international complexion, and the spontaneous welcome accorded by the Japanese has given it truly national importance.

Voyage to Japan.

In the November issue of this journal (page 564) an account was given of the San Francisco meeting which lasted from Oct. 10 to 16. As we stated then, the meeting was in reality a fête, a festival of good things not to be forgotten.

On Oct. 17 eighty-three members and guests of the Institute left San Francisco on the steamship *Manchuria* of the Pacific Mail S. S. Company, bound for Japan, there to be guests of the forty Japanese members of the Institute.

Honolulu, in the Hawaiian Islands, was reached Oct. 23, and a most interesting day spent visiting the sights in and around that city. Most of the party took a 25-mile automobile ride, dined at the Maona Hotel on the famous Waikiki beach, and some even tried the surf riding in catamaran canoes. Under the present government régime the islands appear to be making vast strides in material and educational progress, and everyone seems to be well satisfied with the result.

The stretch of 3500 miles from Honolulu to Yokohama was covered in ten days of beautiful semi-tropical sailing. The voyage was enlivened by frequent entertainments.

Dr. R. Kanda, of Japan, who had come over to America for the express purpose of accompanying the visitors across the Pacific, gave three interesting lectures on Japan, the country, the people, and the language. Mrs. C. H. Sleeper lectured on "Life in Manila."

Mr. D. W. Brunton described "The Laramie Tunnel," a paper eliciting a spirited discussion and comparison of European and American tunneling practice. Mr. W. L. Clark opened up an afternoon's discussion of the proposed "New Mining Code," in which everything from Alaska coal to labor unions was discussed. The writer of this report occupied an afternoon describing the new electrochemical industries of Norway and Sweden.

Among the lighter amusements were a fancy dress masquerade ball and a complimentary dinner extended to the Engineers by the steamship company.

On Nov. 3, several hours ahead of time, the steamer reached Yokohama, and the real goal of the trip, the making acquaintance with Japan and the Japanese, began then *instanter*.

PARTY AT NIKKO COPPER REFINERY.

There are forty members of the Institute in Japan and they were one and all enthusiastic in their reception of the eighty-seven visitors; add to this nucleus the hearty co-operation of over 200 others who also belong to "Who's Who" in the mining world of Japan, and the no less cordial interest of many men high in affairs of state, and the nature of the welcome accorded can be more easily imagined than described.

Baron Shibusawa was chairman of the reception committee, which acted in a very graceful and generous manner, Dr. Wada (an honorary member of the Institute) was prominent upon it, and with T. Dan of the Mitsui Company, R. Hotta of the Mining Institute of Japan, R. Kanda, Prof. B. Katsura of Kyoto, R. Kondo of the Oshio R. R., K. Kato of the Tokyo Chamber of Commerce, K. Nambu of the Associated Mine Owners, Engineer K. Noro, M. Otagawa of the Furukawa Mining Company, Prof. W. Watanabe of Tokyo, and S. Yamanouchi of Takata and Company, constituted the general reception committee.

Dr. R. Kanda was sent by this committee to San Francisco to greet there the visitors and to accompany them on their journey—a courtesy which was highly appreciated, for Dr. Kanda was in position to give the party most valuable and

SMELTING WORKS AT SHISAKA ISLAND.

useful information concerning Japan on their seventeen-day journey across the Pacific.

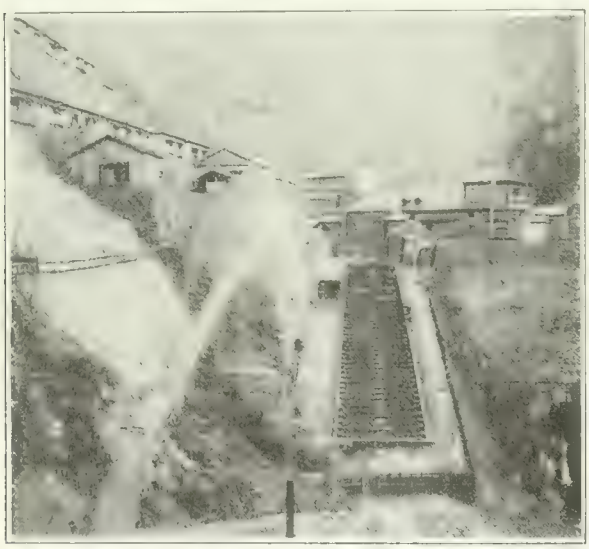
After a memorable day spent in Honolulu and ten more days of comfortable steaming toward the setting sun, the "Manchuria" anchored in Yokohama harbor early on the morning of Nov. 3—the Emperor's birthday. The first rays of the rising sun gilded the snowy summit of sacred Fuji, clearly visible in all her glory, 40 miles away, and when its later rays showed the vessels in the harbor gay with bunting and the city in festive array the scene was charming and the impression ineradicable.

BARON KICHIZAYEMON SUMITOMO.

Representatives of the reception committee were on the steamer early and the round of pleasure had begun. To describe in detail all of the numerous receptions accorded the party would be impracticable, yet so spontaneous were they and so cordial that each one deserved special mention.

In general, the procedure was as follows: The visitors were met at the landing place or railway station by the local committee, the mayor and other officials of the town, also a host of the populace, and an address of welcome was made. The party was then conducted in automobiles, carriages or jinrickishas, gaily decorated, to the town hall or a company's office, where amid gay decorations refreshments were served, badges of welcome distributed and more formal speeches of welcome given and responded to.

The gentlemen then divided into parties to visit near-by mines or industrial works, while the ladies were further entertained by visits to temples, gardens, and the fascinating shops.



CEMENTATION PLANT NEAR THE THIRD ADIT MOUTH, SUMITOMO COPPER MINE.

Comfortable, even luxurious, hotels were found everywhere we stopped, and the evenings were usually devoted to a banquet, followed by dances by "Geisha Girls," and frequently a display of fireworks. At times every one was supplied with flags and decorated with flowers in the enthusiasm of the final moments.

Such were the general features of the reception everywhere accorded, and often the smaller the place the larger the welcome. Ten different badges of welcome were distributed and the mint at Osaka struck off artistic memorial medals in silver as permanent souvenirs of the trip.

The general outline of the eighteen days' travel in Japan was as follows: First reception at Yokohama; two days at Tokyo, with official reception; a day at Kyoto, the ancient capital; visit to Nara; three days on steamer on the Inland Sea, covering visit to Shisaka copper smelting works, the sacred island of Myajima, the government steel works at Yawata and the towns of Moji and Shimonoseki; one day at the port of Kobe; a day at Osaka; two days again at Tokyo; two days at Nikko, including visit to the Nikko electrolytic copper refinery of the Furukawa Company; a day at Kamakura; a day in the mountains at Myanoshita, near to grand old Fuji; and a final winding-up day at Yokohama before sailing for home on the "Siberia."

Side trips were taken by smaller parties from Moji to the great Miiki coal mines and from Nikko to the Ashio copper mines and smelter. The noteworthy particulars of the various visits, reporting them from the technical point of view, are as follows:

Shisaka Island Smelter.

This is a copper smelter belonging to the Sumitomo firm, and located on an island in the Inland Sea. The house of Sumitomo, with headquarters in Osaka, has been in the mining and metal business for nearly two centuries; the present head of the firm is Baron K. Sumitomo, a young man of forty-seven years who looks barely thirty. The firm runs a bank with fifteen branches; its industrial enterprises comprise a coal mine in Kyushu employing 2500 men and furnishing 800 tons of coal daily and coke for the smelting works, the Besshi copper mine, the Shisaka smelter, a metal-working plant in Osaka employing 900 hands manufacturing sheets, rods, bars, tubes and wire of copper, brass, bronze, zinc and aluminium, as well as insulated wire and electric cables, and a steel foundry with 600 hands, using one basic and one acid-lined open-hearth furnace, making wheels, axles, gears, cylinders, ore crushers, dredging machinery, ship machinery, etc. The policy of this firm of thus manufacturing into final form its own crude material is to be highly commended as the wisest industrial policy for the enrichment and development of Japan.

SHEET MILL, SUMITOMO COPPER WORKS.

Coming back to the mine and smelter the visiting engineers visited only the latter, but a few words may be said about the mine. The Besshi copper mine was discovered in 1690 and has been continuously worked since then by the Sumitomo firm. It is in the mountains, 3000 to 4000 ft. above sea-level and 12½ miles distant from the seacoast. The ore deposit is a mile long and 2 to 25 ft. wide, consisting of copper pyrites and pyrite contained in crystalline schists.

The daily output averages 600 tons of 4 per cent copper ore, carrying 35 per cent sulphur, 35 iron, 15 silica, 7 alumina, 1.5 lime, and 1 magnesia.

The mine water, estimated to carry 180 tons of copper a year, is run over scrap iron to precipitate "cement" copper, and the waste is run into the sea by a 10-mile long ditch in order to protect the intervening agricultural lands. The precipitate obtained by means of this process carries 80 per cent copper.

A central water-power plant is being constructed, 25 cu. ft. of water per second being available, with 2000 ft. fall, which will produce 3000 kw.

The smelter was originally on the coast near to the mine, but the smelter gases damaged neighboring farm lands to such an extent that the government appointed a commission to study the question and make recommendations. This commission, on which were Prof. W. Watanabe, of the Mining Institute of Japan; J. Yokobori, professor of metallurgy in Kyoto University; Y. Watanabe, professor of metallurgy Kyushu University, and M. Oshima, professor of metallurgy in Tokyo University, besides experts in agriculture and forestry, recommended the removal of the smelter.

As a consequence in 1901 the works was moved to Shisaka island, 9½ miles from the coast in the Inland Sea. Even at this distance the smelter gases (containing about 2 per cent of SO^2 and 1 per cent of SO^3 at the stack) damage the young vegetation, and it is customary to reduce the running of the smelter two-thirds for twenty days in April or May to save the young rice, and a like period in August or September to protect young barley.

The smoke and fume question is a universal bugbear and the solution adopted by the Sumitomos is indeed instructive.

As for the island smelter itself its location was visible 10 miles across the sea from the cloud of white smoke. The island is entirely occupied by the works and the workmen's village. The population turned out *en masse* to receive us, their interest being partly accounted for by the statement that no foreign white ladies had ever before visited the island; many of the inhabitants are born, live and die there, without once leaving it. Fireworks and frequent *banzais* testified the heartiness of the welcome.

The average laborer is paid 30 cents per day; women, boys and girls receive as little as half that. It should be mentioned, however, that the company supplies houses nearly rent-free, and furnishes supplies at their wholesale cost, sometimes even cheaper for such staples as rice and sugar.

A fleet of 180 lighters brings ore, coke and supplies from the mainland. Numerous stalls of the Freiberg pattern are used for roasting. Five smelting furnaces are working, four with 10 to 13 per cent of coke on ordinary smelting and one with 3 to 6 per cent of coke operating by a semi-pyritical process.

BLAST FURNACE OF THE IMPERIAL STEEL WORKS, YAWATA.

Fine ore is sintered in six pot-roasters 10½ ft. in diameter by 3 ft. deep, in which a 10-ton charge of ore, sand and flue dust is roasted from 20 per cent sulphur down to 5 or 6 per cent in 4½ hours. This finely designed plant was just starting in operation; it was designed by their able metallurgist, K. Nakamuro, with the assistance of H. Kudo, mechanical engineer.

Noteworthy were the overhead crane for lifting the pots and placing them on dumping trunnions at one end of the plant, and the use of an agglomerator to prepare the moistened charge by balling it into small pellets as it passes through a rotating conical barrel. The latter device produced pellets about as large as peas and it was stated that 30 per cent of the time of a blow was saved by putting the material into this shape. The six pots produced 360 tons of sinter per day.

The smelting furnaces are 4 by 24 ft. at the tuyeres, with settlers 10 ft. in diameter, and produce 18 to 23 per cent copper matte, average 20 per cent. The slag is granulated by a heavy stream of water and run into the sea; it averages 0.2

GENERAL VIEW NIKKO COPPER WORKS.

FURNACE ROOM, NIKKO WORKS.

per cent copper. A bank of by-product coke ovens, producing 48-hour coke, is on the island. The surplus oven gas is burned under steam boilers by an ingenious form of burner.

The matte is roasted in stalls and smelted directly to black copper. This is refined in two reverberatories and cast into ingots branded "K. S." This ingot copper carries about 0.015 per cent silver and 0.0003 per cent gold ($2.25 and $2 worth per ton respectively).

The annual output is now 6500 tons of copper, 99.7 to 99.9 per cent pure; it is estimated that the firm has produced altogether 200,000 metric tons of copper from this Besshi ore.

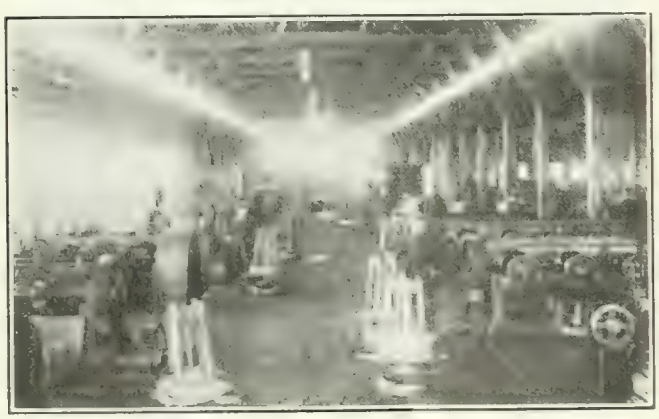
ELECTROLYTIC REFINERY, NIKKO COPPER WORKS.

The Sumitomo firm, like several other similar firms in Japan, gives us the somewhat novel impression of being run and managed more for the best interests of the country and people than for the aggrandizement of the firm; it co-operates with the government in minimizing damage to agricultural lands by smoke, it re-forests the mining lands, it takes a paternal interest in its employees, and it is actively fostering manufacturing industries which after all are going to be the backbone of Japanese progress toward wealth and power. We heartily wish the firm continued success in developing its broad and far-sighted policies.

The Yawata Imperial Steel Works.

This fine works, established ten years ago, situated on a branch of the Shimonoskei Strait, near to the Japan Sea, is the largest and most interesting in Japan.

The pig-iron part comprises three blast furnaces erected by Lührman, in German style, and run under the direction of



DRAWING FINE COPPER WIRE, NIKKO WORKS.

Engineer T. Kawai. Each furnace has four stoves, of which three are in constant use. The output of each is 160 to 180 tons daily.

The ore comes from Hokaido and Corea, and carries 0.5 per cent sulphur. The coke carries 1 per cent sulphur.

The chief point noted about these furnaces was the low pressure of blast, 4 to 5 lb. per square inch. We cannot but think that an American manager would find a way of driving these furnaces at a considerably greater speed.

The pig iron made is rather high in silicon and manganese, and the management fears that higher blast pressure would

ROLLING COPPER RODS, NIKKO WORKS.

still further increase these, but faster running might be so accomplished as to give less silicon; the high silicon is really the result of slow running.

A fourth furnace is contemplated, the dimensions of which will be as follows: Internal capacity, 525 cm; height, 21 m;

PRODUCTS OF NIKKO COPPER WORKS.

diameter of crucible, 4 m; diameter of bosh, 6.8 m.; estimated output, 250 tons daily; raising the total works capacity to 750 tons. The furnaces are well built, with good stove capacity, and should really be driven at considerably higher capacity.

GENERAL VIEW OF SMELTER, ASHIO.

Coke is produced at the works in one bank of Coppee ovens and one bank of Solvay ovens. The product is 600 tons of

coke daily from 1000 tons of Kyushu coal; surplus oven gas is used in the 160-ton pig-iron mixer.

The steel department contains two acid-lined Bessemer converters, which are run in the same leisurely manner as the blast furnaces, a 10-ton heat being blown in twenty-five to thirty minutes. The steel produced cast excellently and rolled

SETTLING AND FILTERING PONDS, ASHIO

finely. There are also eleven open-hearth furnaces of 25-ton capacity each; eight more 50-ton furnaces are being built.

The foundry contains three cupolas and a 15-ton acid open-hearth furnace for steel castings; also crucible steel capacity for 5 tons per day for making special steels and high-speed tool steels. An electric furnace for replacing the crucibles is being figured upon.

With common labor paid 20 to 35 cents per day many things are possible at this plant which would be impossible in the United States, but yet steel making is strenuous work in which muscular exertion is at a large discount wherever machinery plus intelligence can be used.

The Japanese are intelligent, not only the managers but the workmen, and since the latter can be taught to handle machinery we are of the opinion that much further mechanical development at this works is not only possible but probable. Hand filling of blast furnaces should be abandoned, also dump filling of coke ovens, and many labor-saving devices now used in America could be introduced with profit in various parts of the works.

The works produces a great variety of materials, each on a rather small scale, but it has been of inestimable value in the recent industrial development of Japan. We predict for it still further improvement and still greater usefulness to the country in the future.

The coal and steel barons of Kyushu, the Pittsburgh district of Japan, entertained the visiting engineers right royally at the town of Moji, the extreme western point of the trip; everyone felt the warmth of the welcome and also felt at home in the smoky atmosphere and bustling activity of this busy neighborhood.

The Nikko Copper Works.

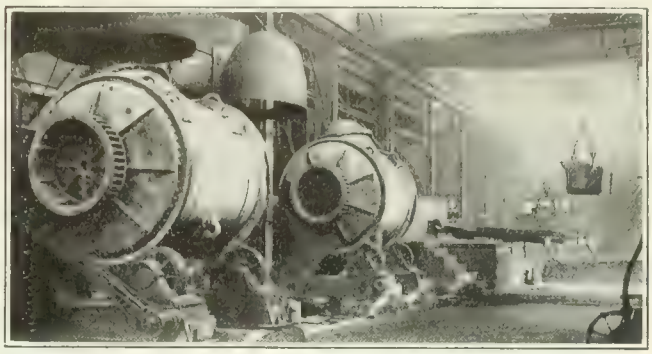
Ninety miles north of Tokyo is the most-visited spot in Japan—the famous shrine of Nikko. Here amid lofty cryptomerias, surrounded by towering mountains, the great Iyeseyu built the group of lacquer and gold temples and his impressive mausoleum which attract visitors and pilgrims from far and near.

But in addition to these standard attractions we were here the guests of the Furukawa Mining Company, which has its great copper mine at Ashio, 18 miles away, and its refining plant on the outskirts of Nikko itself.

This large company, founded only thirty-five years ago, operates fifteen copper mines, two silver mines, one gold mine, one lead mine, four coal mines, a copper refinery and a coke plant. Its working force is 22,000 men and it produces yearly 14,000 tons of copper, 700,000 ounces of gold and silver, 500,000 tons of coal and 30,000 tons of coke. The present head of the company, T. Furukawa, is only forty-seven years old; he accompanied the visitors throughout a large part of their trip.

A small company of about a dozen left the main party at Nikko and rode horseback over the mountains to see the Ashio mines and smelter. These mines were discovered in 1609, but when bought by this company in 1877 were producing only 52 tons of copper yearly; under the enterprising management of the Furukawas the production has reached 7000 tons annually. The deposit consists of a mountain about 2000 ft. high, worked from four different directions, and in which over fifty veins of copper ore are being mined.

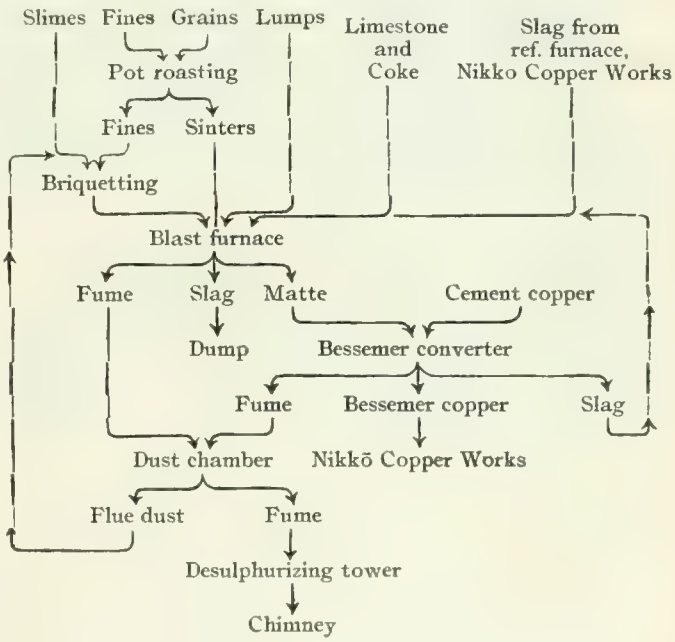
There are three large concentration plants. The mine water is run over scrap iron, producing 36 tons of cement copper monthly; the waste water, together with the slime-carrying



INTERNAL VIEW OF ASHIO SMELTER.

water from the concentrating plants is treated by a special process before discharging into the river, in order to render it harmless to the rice fields which it irrigates.

The ores are chiefly chalcopyrite, pyrite, quartz and some sphalerite and galena. They go to the smelter as lump, grain,



SMELTING SCHEME, ASHIO WORKS.

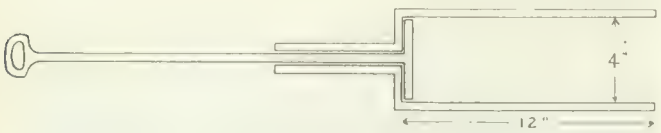
sands, slimes, cement copper and copper precipitate. About 60,000 tons of material, averaging 12 per cent copper, is smelted per year.

The precipitation of the waste waters deserves mention. Lime is used as the precipitant but when used all at once the precipitate was too poor in copper and too high in silica and alumina to pay smelting charges; by first running in a small part of the milk of lime the bulk of the iron, alumina and silica is precipitated first, while afterward the further addition of lime gives a precipitate rich enough in copper and low enough

in alumina to stand smelting. The details of this ingenious process have been worked out by Mr. Imai, who promises their early publication in the Bulletin of the Institute.

The smelter plant consists of pot roasters, rectangular smelting furnaces and Bessemer converters. The blister copper ingots are sent over the mountain by rope tramway to Nikko for refining. The outline of the plant is given in the diagram of the smelting scheme on bottom of page 19.

The following items caught our attention as worth mention and comment: The briquetting press was of novel design, patentered by S. Watanabe, mechanical engineer of the company.



CHARGING DEVICE.

It operates like a stamp mill, each briquet being moulded by six stamp blows of 120 lb., falling 10 to 12 in. Two horsepower suffices for a daily production of 36 tons.

The briquets were dried by being piled around hot cones of slag. The machine was ingenious, very cheap and reasonably effective.

Eleven pot roasters in operation serve to prove the success with which the Japanese have adapted this method to the needs of copper metallurgy. A smelter charge taken from the black-board alongside the furnace was:

Lump ore	300 lb.
Grain ore	100 lb.
Briquets	200 lb.
Pot roast sinter	400 lb.
Converter slag	150 lb.
Limestone	325 lb.
Coke	100 lb.
Coal through tuyeres	30 lb.

The last item deserves special mention. Each tuyere has an outer-flap valve about 5 in. in diameter, in which is a smaller ¾-in. swinging valve. Through these two workmen are con-

TRANSPORTATION OF BESSEMER COPPER, ASHIO.

tinuously employed at a furnace smelting 100 tons per day in introducing soft bituminous coal into the furnace.

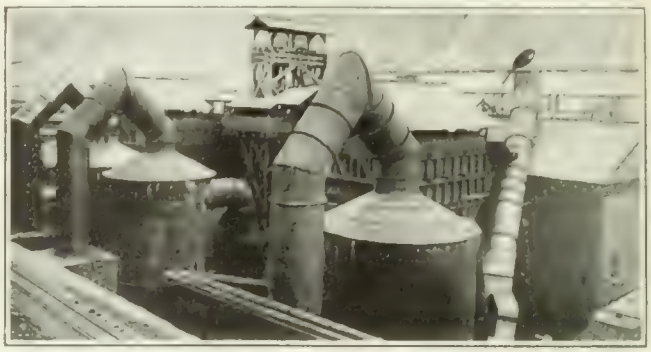
The coal is in lumps of ½ to 1½ in., and is put first into a charging cylinder 4 in. in diameter by 12 in. long, provided with a piston worked by a rod through the handle.

This implement was turned up, filled with coal, thrust rapidly into the tuyere, and the contents then discharged by pushing the handle operating the piston. (See above diagram.)

After three or four cylinders had been thus put in at one tuyere it became necessary to use a poking rod, through the small valve, to clear the tuyere and get all the coal into the furnace.

About 3 tons of coal is thus put into each furnace per 24 hours. The men's wage is 30 cents each, per 12 hour shift. The superintendent explained that this practise kept the smelting zone hotter, prevented the tuyeres from building out "cold noses" into the furnace, nearly eliminates the necessity of barring down charges from above, and increases the smelting capacity of the furnace.

The practise is common at other Japanese copper smelters; in fact it is said that at the Kosaka smelter, working ore with

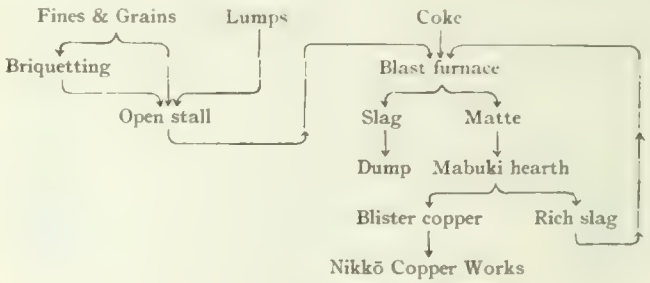


DUST CATCHER OF ASHIO SMELTER.

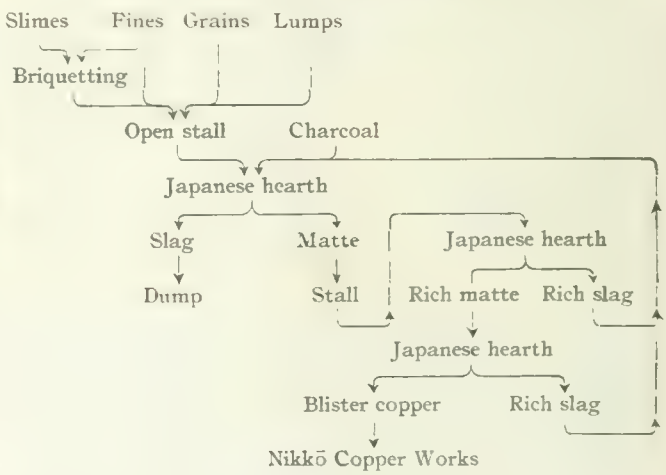
40 per cent of barite, it was found impossible to run the furnaces without this introduction of coal at the tuyeres.

It is certain that the effect is advantageous and American engineers should be able to devise an automatic stoker to put in the coal mechanically if they ever decide to adopt the practise.

The Ashio smelter now bessemerizes its matte in two acid-lined converters, which blow 10 tons of matte (in two successive charges of 5 tons each) in 10 hours, to 4 tons of cop-



SMELTING SCHEME, FURUKAWA WORKS.



SMELTING SCHEME, NAGAMATSU WORKS.

per. The only noteworthy feature of this operation is that one converter lining lasts only two blows—an unnecessarily short life from an American point of view. It appears probable to us that properly directed effort could at least double the life of these linings.

Of great metallurgical interest is the fact that these converters have replaced an old Japanese process which was practically a "hearth-Bessemer" operation; it was called the "Mabuki" process or "Japanese hearth," and is still operated at

some other copper smelters, such as Furokura and Nagamatsu, diagrams of whose smelting schemes are given on page 20.

The "Mabuki" process or "Yamashitabuki" was invented at the village of Yamashita, near Tada, province of Settsu, nearly 400 years ago. The Japanese smelting hearth is made in the ground with stone walls cemented with clay and lined with brasque.

Common dimensions are 24 inches diameter by 10 inches in depth, with one tuyere 1 in. in diameter, others are 36 in. by 16 in., with 2½-in. tuyere; the charge is ½ to 3 tons of matte, using 50 to 30 per cent of its weight of charcoal.

At Furokura there are six hearths, each 32 x 15 in. and capable of working a charge to 6000 lb. of 45 per cent copper matte down to blister copper, 98.5 per cent pure, in 24 hours.

At Kusakura a similar hearth is operated with air blast and oil spray as fuel, instead of charcoal.

At Nagamatsu the hearth is used also as a smelting furnace, 5000 lb. of roasted ore being smelted to 35 per cent matte in 10 hours, using 1500 pounds of charcoal.

The slag being pulled off, water is sprinkled on the surface of the matte, which is then stripped off in thin sheets. This matte is partly roasted in stalls, and again smelted by a similar operation to 60 per cent matte.

This second matte is roasted in stalls and smelted to blister copper in the hearth.

This process, as a whole, is the Welsh process, operated in hearths instead of reverberating furnace, but where the hearth receives molten matte directly from the shaft furnace the operation is really "bessemerizing" of matte upon a hearth. The operation is an interesting metallurgical "survival" from the olden times.

The Ashio smelter furnishes one more interesting feature to the metallurgical tourist, viz., an attempt to suppress the chimney gases. The photograph of the plant shows four towers in series on the side of the mountain between the works and the chimney.

These are brick towers 12 ft. square by 42 ft. high, down which (through 200 holes of 0.4 in. diameter) milk of lime is showered. The gases average 0.8 per cent SO^2 and 0.3 per cent SO^3. By using 40 cu. ft. of water per minute and 300 lb. of burnt lime per hour, in the towers, all the SO^3 is intercepted and 40 per cent of the SO^2, reducing the latter to 0.5 per cent.

The water, containing much SO^2 in solution, is run into settling ponds, more lime there added, and the clear waste water filtered through sand before being discharged into the river. The government evidently considers this as a fairly satisfactory solution of the smoke and fume question at this particular smelter.

Between the smelter and refining works at Nikko the company has at Hosoo a 6000-kw. power plant.

The water supply of 5 cu. meters per second as a minimum comes from the Daiya River, fed by Lake Chuzenyi. The upper power house, containing one 2000-kw. unit, has 643 ft. head, the lower house, with two 2000-kw. units, has 714 ft. head. The generators are built by the Siemens-Schuckert Co., and are 11,000-volt, 3 x 109-amperes, 50-period, 2000-kw., 375-r.p.m. machines with a power factor of 0.77. The power is transmitted 13 miles to the Ashio mines and smelter and 2 miles to the Nikko refining plant. Another 2000-kw. unit is to be added.

The Furukawa Company entertained the whole party of the Institute visitors at luncheon at the Nikko works, where a remarkable reproduction of the famous red-lacquer sacred bridge of Nikko was build up of copper wire-bars, with the stream represented by blue vitriol crystals. The copper used was one day's output of the works. At Ashio the smaller party was received with great enthusiasm; an archway erected at the office gate (see photograph) had pillars of Bessemer bars, representing likewise one day's output of the works.

The Nikko works receives copper from the various smelters of the Furukawa Company, the blister copper from "Mabuki" hearths and Bessemer converters, and produces annually 2000 tons of ingot copper, 5000 tons of copper wire, 500,000 ounces of silver bullion, besides copper sulphate crystals.

The blister copper containing too little gold and silver to pay for electrolytic refining is melted, furnace refined and cast into commercial ingots averaging 99.7 per cent pure.

There are four refining and casting furnaces, two of which have casting machines, the capacity of each furnace being 40,000 to 55,000 lb. per heat. A run in such a furnace comprises 4 hours charging, 8 hours melting, 4 hours refining and poling, 4 hours casting. Workmen around the furnace receive 25 to 50 cents gold per day of 12 hours.

The casting machine is of Japanese design, being the invention of Mr. Kuku, mechanical engineer of the company. It resembles the simple semi-circular pig lead casting device used in lead works, except that the iron pipe is replaced by an open launder pivoted on the spot where the stream of copper falls from the furnace.

The outer end of this launder carries a separate tilting section whose outer lip can be raised while the stream is being transferred from one mould to another, the section being hung

PARTY AT ASHIO. PILLARS OF GATEWAY ONE DAY'S OUTPUT BESSEMER BARS.

upon a lever operated by the man who swings the launder. One man regulates the flow of copper from the furnace, a second moves the launder and regulates the casting, a third dumps the moulds and rights them again. The apparatus is cheap and effective and its operation very simple.

Blister copper for electrolytic refining is first furnace-refined up to about 99.44 per cent copper, and then cast into slabs 12 x 20 in., 1 in. thick. These are heated to redness, rolled down to ¼-in. thickness and then cut into pieces 12 x 24 in., weighing 20 lb. The edges are frequently curved and ragged. Two of these sheets form one plate in the refining tanks, the side edges being painted half-inch wide with asphaltum varnish.

There are 300 refining tanks, run on the series system, a current of 600 amperes being sent through four tanks in parallel. Twenty-five such sets in series are run on a 250-volt circuit, there are three such circuits. The drop is 10 volts per tank, and, with 26 electrodes per tank, this is 0.38 volt per electrode.

The current density is 38 amperes per square foot (418 amperes per sq. meter). The distance of the electrodes apart 1 to 1.5 in. (2.5 to 4 c. m.). The ampere hour efficiency is about 35 per cent. The circulating solution is 5 gal. per min. per tank. Ten per cent. of total electrolyte are purified every two weeks. The excess of dissolved copper is sold as blue vitriol.

The very low current efficiency is doubless due to the large path for current to pass below and above the electrodes and

at the center between the plates. About 10 c.m. space was allowed for accumulation of slimes below the electrodes, and as much as 3 c.m. of solution was seen in many tanks above the electrodes; the plates had curved or ragged edges, so that where they met in the center of the electrode considerable free space, probably averaging one inch, existed.

The total area of free path for current was thus some 6 in., against 24 in. of copper surface. This would easily account for 50 per cent loss of ampere hour efficiency in such a 26 electrode series tank. Part of the low ampere hour efficiency is probably also to be ascribed to running the plates until within 5 per cent of the original electrode is dissolved, which would entail redissolving and reprecipitating considerable pure copper.

This practise gives very low anode scrap to be remelted. The anode residue is removed from the cathodes by hand chipping with chisels. Altogether, the plant is interesting, and particularly so because of the room for technical improvement.

The visiting engineers certainly owe a large debt of appreciation to the Furukawa Company for the hospitality lavished upon them, for the very instructive information gained at its mines and works and for the personal attentions most numerous and acceptable received throughout the trip from the president and professional staff of the company.

Afterthoughts.

We travel to enlarge our mental horizons, to make friends, and, if possible, to help those we visit.

Not one of the engineer pilgrims to Japan but will acknowledge the gaining of much information and mental improvement from the trip. We found the Japanese the greatest eclectics of the age; they have selected from abroad and adopted with the greatest discrimination those ideas and processes which are best adapted to their conditions and needs.

In the line of mining and metallurgy Japanese graduates of Freiberg and Clausthal are numerous, and German methods were more in evidence than American. This is most intelligent discrimination, for their labor conditions and resources to work with are much more similar to those in Germany than to those in the United States. We believe, however, that as time passes and conditions change future development will more and more approximate to the methods we use.

Even in philosophy and religion the educated Japanese shows the same eclecticism and discrimination. He is fusing together the best principles of Buddhism, Confucianism, Shintoism and Christianity into a code and rule of life which, as far as high thinking and right living are concerned, may be regarded as a religion of high practical value as well as pure ethical ideals.

Japanese engineers have also frequently improved upon their teachers, so that evidences of inventiveness and originality in mining and particularly in metallurgy are frequently visible and give the professional visitor ideas to take away with him.

Friends, appreciative and sincere, we feel that we have numerously added to ourselves, to beautify our sentiments towards Japan and to enrich our lives.

Turning our thoughts Japanwards, have we any useful ideas to give them? Is our generous appreciation of their magnificent half-century's accomplishment and advance in modern ways not tinged with a slight note of regret?

Let us acknowledge that it is, and with the kindest of intentions here give the thought expression. Fifty years ago "the door was opened," foreign influences poured in like a flood, the best fruit of European civilization dropped full-ripe into the outstretched hand of Japan.

But modern civilization is, in its essence, a continuing progress, its best is always becoming better, and no part or component unit of it can exist independent of the whole. We have found our Japanese friends, so believe some of us, too prone to cut themselves off from the outside influences which have largely made the new Japan, too eager to do everything for themselves, too anxious to feel independent of outside help.

Such tendencies are to be seen in the general exclusion of foreigners from management and [illegible] and smelters, in the backwardness [illegible] Japanese to take an active part in international scientific societies, in their growing disinclination to master English, German and French, and particularly in the general exclusion of foreigners from the faculties of universities and technical schools.

The professional Japanese of the passing generation are much more cosmopolitan in their inclinations than the rising generation; the latter appear in general much narrower in their sympathies and aspirations. It appears, therefore, that the intellectual stimulus of foreign origin is being largely shut out, that the idea of the sufficiency of Japanese for the needs of Japan is gaining ground, and that "the open door" is largely for "beans" rather than for "brains," for commerce rather than for intellect.

In taking this position the Japanese are making a mistake of huge proportions. They fail to take into account the incubus which the mass of their population is to modern progress, the immense drain upon the upper classes in the training of the lower, the great drag on the intellectual resources of the educated Japanese which his environment and daily contact with the people force upon him.

The educated classes of Japan are not alone sufficient to the task before them; they themselves are constituted more than half "old Japan" in feeling, thought and sentiment. They can lead their people, but they still require the external stimulus of intellectual intercourse with foreigners, liberally applied, to prevent discouragement and retrogression.

Perhaps the reflex of a recently successful war has something to do with this overconfidence in the intellectual self-sufficiency of the Japanese for Japan. Whatever the cause, the pendulum has swung too far; the previous policy may have been unnecessarily liberal in utilizing foreign assistance, but the present policy is undoubtedly too stringently excluding it.

Let us hope to see, in the near future, more foreigners managing and superintending mines and smelters, more Japanese active members of international scientific societies, more professional Japanese masters of the English, German and French languages, and more foreigners of high ability upon the faculties of their universities and technical schools.

This is the best that we can wish for Japan, and may it thus maintain its marvelous crescendo of progress.

Discussions at San Francisco.

To supplement the report of the San Francisco meeting which appeared in the November issue, the following abstracts of some of the discussions will be of interest.

Alaska Coal was the subject of a spirited discussion, led by Mr. H. Foster Bain, editor of the *Mining and Scientific Press*. Mr. Bain urged that some kind of public control of the Alaska coal deposits is desirable, and that the simplest form of control yet found is ownership. However, in his opinion, government ownership of a part of this coal, say one-third, would attain the desired end of preventing individual monopoly of the field. From this reserved land the government itself should mine coal to supply the needs of government vessels or railways. Further, the government should lease coal lands to individuals on liberal terms, for a fixed period, such as 25 years, at a low royalty, the number of such leases being restricted to correspond to the probable market, so as to prevent overproduction and consequent waste.

Dr. R. W. Raymond, secretary-emeritus of the Institute, ridiculed the above proposition as impractical and un-American. He believed in as little government as possible, and that it was puerile to substitute a government monopoly for the dreaded individual monopoly.

The fallacy of Dr. Raymond's protest was, however, cleared up by a member pointing out that "monopoly" by the government, in the interest of the people as a whole, was an entirely different matter from monopoly by private individuals in the

interest of private capital and at the expense of the people as a whole.

One sentence of Dr. Raymond—"You cannot cure national evils"—was so brutally pessimistic and so contrary to facts that his further tirade fell on deaf ears.

The general opinion of those who heard the entire discussion was that while Mr. Bain had not presented an entirely satisfactory solution of the question, yet something, along some such lines, should be done in order to meet a situation whose dangers were entirely evident to everyone except Dr. Raymond.

Gold Dredging in California was handled very thoroughly by Mr. Charles Janin. He gave the history of the development of the dredges, as means of reaching the deep gravels, 40 to 60 ft. below the surface, which could not be otherwise economically treated. The present dredges cost up to $250,000, handling over 20,000 tons of material per day. By this means alone, the output of gold has risen in California from $18,000 in 1898 to over $7,000,000 in 1910.

Statistics of Gold Production in California were given by Mr. Charles G. Yale. He credited the profession of mining engineers with having done more for the state than even the pioneers, for while the latter often wasted more gold in tailings than they extracted, the former were preserving the resources of the country and utilizing them with a minimum of waste and loss. Counting from 1792 to the present, California has produced one-half of the total gold output of the United States.

California Oil was the subject of a paper by Mark L. Requa, which excited great attention. He deprecated the reckless manner in which the oil resources of the state are being exploited, and commended the action of the government in withdrawing oil lands from entry.

With the present rate of overproduction, oil brings at the wells only 30 cents per barrel, and is handled and gathered so carelessly that the loss by seepage, waste, etc., is estimated at 3,000,000 barrels per annum. With oil at a higher price and more restricted production, much of this waste would be avoided. The opening up of more oil lands would have the opposite effect. At double present prices California oil could compete with Alaska coal along the Pacific coast, from Vancouver to Panama, and at present prices from the Arctic circle to Chile.

The question of opening Alaska coal lands to entry is, therefore, one of no present importance, except for the small demand locally in Alaska. He estimated the total oil supply of California at 8,500 millions of barrels, which is about half of the total oil resources of the United States.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in September, 1911, was sixty-nine. The total tonnage milled during that period was 2,088,522 tons of ore; 10,307 stamps were in operation with an average duty of 7.91 tons per twenty-four hours. Tube mills in commission numbered 235. The yield for the month was 700,625 fine ounces gold. The tonnage treated, number of stamps and tube mills at work, and total yield, all show marked increase over September, 1910.

The Colorado Scientific Society has inaugurated a movement which is being received with enthusiasm by the various mining and milling districts of the state. A series of practical talks by members of the society will be given at various towns, the subjects and speakers being selected appropriate to the peculiarities of the district. The first of these talks was held at Idaho Springs, where Mr. Charles A. Chase spoke on "Mine Management." At Leadville George W. Schneider spoke on the "Application of Business Principles to Mining and Metallurgy." The latest meetings have been held at Telluride and Ouray, where Mr. A. E. Anderson spoke on "Recent Developments in Explosives," and Mr. C. J. Stahl on "The National Forests and the Prospector." Other meetings will be held at intervals throughout the coming year.

Nomenclature of the Microscopic Constituents of Iron and Steel.

By HENRY M. HOWE.

Socrates: "But yet, should we dispute about names if we knew the abilities of such importance to consider?"

[illegible] the [illegible] with clearness."

An attempt is about to be made to adjust and systematize the nomenclature of the microscopic constituents of iron and steel, and on this account some reflections on this general subject may interest your readers.

When we learnt from Sorby and Osmond that steel was composed of several different microscopic substances, each of which was important for one reason or another, we saw that we needed short names for these substances, so that we might the more easily speak and write about them. Thus during the last quarter of a century a distinct nomenclature has sprung up which has been of great convenience. Unfortunately, usage has not been strictly consistent. A given name, for instance "sorbite," has been used by some in one sense, by others in a slightly different sense. The International Association for Testing Materials has appointed a committee to report on this subject at its coming congress in New York in September, 1912, in order to prevent further confusion by giving the several names clear and consistent definitions. On this committee are specialists from the chief countries in interest, France, Germany, Great Britain, Sweden and the United States.

That uniformity in nomenclature is needed here as it is everywhere else nobody will question. But serious obstacles present themselves, as to which I should like to say a few words. I believe that in the last analysis they are due to misconceptions as to the functions and limitations of language in general, and as to the needs of such a nomenclature in particular. This I will try to show as I explain the general conditions.

When molten steel solidifies it forms what is called a solid solution of iron with carbon, the molecular constitution of which does not concern us here. This is called by most writers "austenite," by others "gamma iron" and by others "mixed crystals." When steel first solidifies the whole of the carbon present is in general contained in this austenite, so that austenite may have any carbon content up to about 1.7 per cent. In cooling slowly this austenite is transferred progressively, in passing down through a certain critical or "transformation" range, into a granitic conglomerate consisting of (1) particles of relatively pure iron, mechanically mixed very intimately with (2) other particles of the definite iron carbide, Fe_3C, in a fixed ratio of about six of iron to one of carbide; and (3) in addition further particles, more or less abundant, of either such iron or such iron carbide, according to the carbon content of the whole. The particles of nearly pure iron are called *ferrite*, those of the iron carbide are called *cementite* and the intimate mixture of these two in the ratio of 6:1 is called *pearlite*.

When cast iron solidifies it forms a like solid solution or austenite, and in addition more or less graphite and cementite. During its slow cooling part of this cementite breaks up into a mixture of graphite and austenite, a change which we need not consider here; but its initial austenite, like that of steel, transforms, in cooling down through the transformation range, into a like granitic conglomerate of pearlite with either ferrite or cementite, according to the carbon content of the austenite itself which thus transforms.

Were this all, though it might be complex enough, it would not be likely to give rise to any serious differences as to nomenclature. Unfortunately for purposes of explanation and nomenclature, this transformation from austenite is a sluggard and a laggard, though in fact its very sluggishness is of inestimable value to mankind. Just as we should be basely ungrateful if we complained of friction, because without friction no man or

beast could stand erect an instant, and every unreinforced masonry structure would at once fall down, so we should be profoundly grateful for the complications which arise through the sluggishness of this transformation, because to this sluggishness we owe the hardening power of steel, and the various ways of bettering it by heat treatment. In the same way we owe the transparency of glass to its sluggishness in transforming into its opaque state of true equilibrium, a sluggishness without which we should be housed without daylight, and should be almost wholly ignorant of chemistry, physics and astronomy.

Thanks to the sluggishness of this transformation, and to the sluggardizing effect of the presence of manganese and nickel, we are able to harden steel, by cooling it too fast to allow the transformation to complete itself, and again to mitigate or "temper" the effects of that hardening, by appropriate heat treatment, which allows the arrested transformation to go on to a definite and predetermined degree. That is the welcome side of the sluggishness, that it increases the value of the metal incalculably; its seamy side is that metallographers will quarrel about the interpretation and the names of these various transition stages between the end conditions, austenite before the transformation begins, and pearlite with ferrite or cementite after it is complete.

What are these transition stages?

When steel is cooled with great rapidity from above the transformation range the transformation is arrested in an early stage recognized by its acicular structure, and under favorable conditions even part of the initial austenite may be retained closely intermixed with this acicular substance, which is called *martensite*.

If the transformation is allowed to go a little farther, it may yet be brought in either of two fairly well marked stages, troostite and sorbite, or in the less prominently marked stage osmondite. Most of our troubles as to nomenclature concern these three intermediate stages. Looking broadly at these microscopic substances, both end and transition, two of them are definite chemical substances, the pure iron or ferrite, Fe, and the iron carbide, cementite, Fe_3C; one of them, austenite, is a solid solution, the composition of which, like that of salt water or any other solution, varies by infinitesimal degrees from specimen to specimen, and one, pearlite, is a conglomerate or aggregate of ferrite and cementite in definite proportions.

Ferrite, cementite and austenite are phases, in the language of the physical chemist, i.e. any given specimen when in equilibrium is chemically homogeneous. They are like the minerals of nature, and therefore called "metarals." Pearlite is not a phase but a mechanical mixture; it is called an "aggregate" to distinguish it from the metarals proper. It is on a par with the petrographic entities like granite, syenite or diorite, as distinguished from the true minerals of nature with which austenite, ferrite and cementite are analogous.

As to the nature of martensite, sorbite and troostite, we do not know positively, though there is strong reason to believe that sorbite consists chiefly of the final products of the transformation, pearlite with either ferrite or cementite, emulsified, i.e. in so fine a state of subdivision that they cannot be recognized with the strongest magnification. But that does not here concern us. As long as opinions differ, let us recognize that they do differ, and proceed exactly as if we did not surely know. That can do us no harm in framing or defending our nomenclature.

At the last congress of the association a report was presented which included the transition stages, troostite and sorbite, and less prominently osmondite. The framers of that report could not be present to explain or amend it, and in their absence a different scheme was adopted by the congress. This scheme completely suppressed "troostite" and "sorbite," proposing that "osmondite" should replace both of them. This step seemed to me an error, for the cogent reason that each of the two stages, troostite and sorbite, is of an importance, both micrographically and industrially, to justify retaining its already established name. Beyond this, M. Osmond refused categorically, and, in my opinion, justly, to permit this use of his name.

In effect metallographers have gone right on as if that report did not exist. Most of them have continued to write of troostite and sorbite, and some have continued to write of osmondite. Thus to-day the names of the several stages, martensite, troostite, osmondite and sorbite, are used either by most writers or at least by a group too important to be ignored. In addition the names of the end substances, austenite, ferrite, cementite and pearlite, continue in very wide use.

Under these conditions the duty of the committee in charge seems to me perfectly clear. (1) To interpret to readers the meanings of these various terms as used currently so that the reader may understand what the writer means. (2) To erect boundaries and definitions which shall distinguish the several microscopic substances from each other. (3) Where a given name has been used with different and inconsistent meanings, to advise the abandonment of all but the best, if possible securing the acquiescence of those who have used the meanings which it advises abandoning. (4) Where more than one name has been used to represent a given entity, to record, for the benefit of the reader, all those which have been used to an important extent, and to advise the abandonment of all but the best, as before seeking the acquiescence of the parties in interest. (5) To describe the several substances and to explain their genesis and life history, indicating the more reasonable of the underlying theories.

The task of the committee is made more difficult by the attacks from various quarters made against the existing names.

First comes the charge of the physical chemists, flushed with their late victories over nature, and overconfident of the advantages of their point of view. With their minds set on phases, they assume that only phases deserve a name. One eminent metallographer says "it was certainly better that names should not be given to things which could not find a place on the equilibrium diagram." They would erase the names "pearlite," "martensite," "troostite" and "sorbite," and a fortiori "osmondite," on the ground that those things which they represent are not phases. The position is a natural one, and, in view of the intelligence and importance of those who take it, it certainly must be treated with respect.

They lose sight of a very important consideration, that an existing name may properly be retained if it is useful for any purpose. The equilibrium diagram itself is of the greatest value; yet it is not an end in itself, but only a means toward an end, a useful tool to interpret and foretell. Whenever and wherever a substance or a group of substances is of such importance that the convenience of language calls for a specific or generic name for it, such name will arise, and will continue in use, though all who do not happen to need it should thunder protests to Heaven. The simple truth is that, though each of these several names may be needless for the purposes of the equilibrium diagram, they are of use either for metallographic or industrial purposes, or for both.

How useful names may be which do not find any place on the equilibrium diagram may be understood by seeing how useful, in the closely allied subject of petrography, names are which find no place on the geophysical equilibrium diagram. Clay, shale, schist, etc., are not phases; but they are names of great usefulness, simply because they stand for classes each of which is convenient for purposes of speech.

To this the reply is made that, even if such classes may be named, yet they must not be given the suffix "ite."

But, first, there is nothing peculiarly sacrosanct about this suffix. It is true that most of the modern names of true minerals end in ite; but it is equally true that many of the most typical and best known mineral names do not, quartz, idocrase, tourmaline, psilomelane, galena, and so on by the dozen.

But "ite" is not distinctive of mineralogical rather than

petrographic entities. Granite, trachyte, dolorite, diorite, diabase, hyperite, aphanite, syenite, pegmatite, quartzite, steatite, ophiolite, etc., are not phases, but either conglomerates or special states of aggregation. Most of the petrographic "ites" are not phases.

The reason why these mineral species and these rock species have received specific names is that convenience of speech demands it. It is convenient to have one single name which shall cover all granite, etc., etc.

Then come others who would deny to martensite, sorbite and troostite the suffix "ite" on the ground that they are of variable composition, and others would deny this suffix to even austenite on this same ground. They know not what they say. The suffix "ite" is expressly for the purpose, among others, of naming substances of widely varying composition. It is, indeed, widely and properly used for substances of composition varying incomparably more than the composition of austenite, martensite, troostite or sorbite varies.

Let us take austenite as an example. It is gamma iron containing dissolved carbon which cannot under any conditions so far as we now know exceed 1.7 per cent. It is not necessary to go to the rock substances, granite, syenite, etc., to find such variations in composition, for the true minerals of nature vary incomparably more. What mineral is there which never has one of its essential components, elements or radicals, replaced by another to an extent greater than 1.7 per cent? I take almost at random eight minerals from Dana, with the variations in percentage of one of their essential components.

Chromite:	Ferrous oxide	varies	from	19	to	39	per cent
Spinell:	Magnesia	"	"	10	"	27	" "
Magnetite:	Ferrous oxide	"	"	12	"	29	" "
Dolomite:	Magnesium carbonate	"	"	10	"	68	" "
Ankerite:	" "	"	"	12	"	36	" "
Smithsonite:	Zinc "	"	"	40	"	98	" "
Corundum:	Alumina	"	"	50	"	93	" "
Menaccanite:	Ferric oxide	"	"	2.66	"	94	" "
	Titanium "	"	"	3.55	"	59	" "
	Ferrous plus ferric oxide	"	"	40	"	96	" "

It is quite permissible to regard austenite as essentially gamma iron which may contain carbon dissolved in it. From this point of view the variations in its carbon content are insignificant compared with the variations in composition of the minerals of nature. If austenite must have its queue cut off because its composition is not fixed, which of the names of the minerals of nature shall not deserve like mutilation?

Beyond this, we have no reason to believe that the physical properties of this austenite vary more, with its varying carbon content, than the properties of certain rock species, such as granite, or even mineral species such as obsidian. It is true that the products of the transformation of that austenite arrested by rapid cooling do vary, from pure ferrite in the case of nearly carbonless austenite, through martensite of varying carbon contents, to the mixture of austenite plus martensite present in rapidly cooled steel of 1.50 per cent of carbon. But that is not to the point. With the exception of its fusibility, the properties of the austenite itself, as it exists above the transformation range, have not been shown to vary greatly with its carbon content. Certainly there is no evidence of variations of a kind that make a single specific name like austenite inapplicable to the whole range of the solid solution above the transformation range.

Why are minerals called by their mineralogical names rather than by chemical names? Why do we speak of "corundum" rather than of "alumina"? Partly because corundum, though typically consisting of alumina, is in fact rarely identical with alumina. Indeed it may contain only 50 per cent of alumina. An additional and very strong reason is that the mineralogical name implies nothing either as to chemical composition or molecular constitution.

Here we see at once why the pioneers in metallography selected mineralogical names, (1) because we were and are uncertain or at least in dispute as to the constitution of these microscopic substances, so that a mineralogical name, through its implying nothing on these heads, is appropriate; (2) because the composition of these various microscopic substances varies greatly, so that a chemical name, with its implication of fixed composition, would be inappropriate. Thus the very reasons which are raised for denying the suffix "ite" to austenite, martensite, troostite, and sorbite, that their composition varies and that their constitution is in dispute, are really reasons why their names should be mineralogical. To me these reasons seem amply sufficient.

Next come certain persons of importance who would remove the suffix "ite" from martensite, etc., on the ground that martensite is only a special structure and not a distinct entity. But if that were true it would be no reason at all. Between quartz, quartzite, itacolumite and novaculite the difference is essentially one of structure. So with the varieties of calcite. The names iceland spar, preunnerite, satin spar, aprite, travertine, stalacite, and stalagmite are based essentially on structural differences. So between chalcedony, agate, onyx, flint, hornstone, and jasper the difference is chiefly one of structure. Remember that these last names are exactly on a par with those ending in ite, and the fact that they do not is due solely to their antedating the time when the suffix "ite" was adopted conventionally. So with granite, granulite, pegmatite; their essential difference is one of structure.

A third class, also containing men of importance, objects strenuously to the name osmondite. With reluctance they will allow troostite and sorbite to remain, provided osmondite is stricken out. Their objection is not clearly formulated; but it seems to consist of two parts; first, osmondite is not shown to be a phase; second, it is not necessary to have a name for a stage intermediate between troostite and sorbite. Both these objections they hold against troostite and sorbite also; but they waive them. Let us consider them as applied to all three names.

The first objection we have already seen to be insufficient because it applies with equal force to many true mineralogical names, and to petrographic ones, whether ending in ite or not, so that the enforcement of this principle would be unwise.

Turning now to the question whether these names are needed, it really resolves itself into two, one for the writer and one for the lexicographer, in which latter class the present committee belongs. It is for each writer to decide whether he does or does not need names with nice shades of meaning, such as osmondite and troosto-sorbite. Those who look only at the general outlines and not at the details have no right to forbid the workers in detail from having and using words fitting their work; nor have those whose needs are satisfied by the three primary colors a right to forbid painters, dyers, weavers, and others from naming the many shades with which they are concerned. To the dweller in a perfectly flat country the names hill and plain may suffice; yet those who live in the foothills may well need many more names, rise, swell, mound, hummock, hillock, mountain, crag, butte, canyon, valley, vale, dale, swale, gulley, etc. Stanley told me that the language of the African forest dwellers was incomporably richer than English in names for varieties of growth, forest, jungle, etc., simply because, savages though they were, their environment gave an importance to differences which seem to us unimportant and called for distinctions which to us are superfluous. The smith needs a few words which are needless to the poet, and the poet has thousands which the smith knows not. It would be unfair to either, if it were not futile, to forbid him to use those which are needless to the other.

So much for the aspect of the matter to the writer and speaker. The committee is charged with a lexicographic duty, to teach the reader what the writer means when he uses a certain word so as to help the reader to understand the writer. If the committee goes beyond and explains current theories,

describes the varieties and then censors, that does not relieve it of its first duty, to interpret to the reader the unknown word. It may properly say that such and such a word is rare, or obsolescent, or misleading, or ambiguous, and it may even remonstrate against its use. But when it has done that it has exhausted its corrective powers. It has no moral right to say "We will indeed interpret to the reader the words which please us, but we refuse to interpret those of which we disapprove. Let the reader who meets such words remain in ignorance as to the writer's meaning or let him find out as best he may; we owe him nothing, and we refuse to enlighten him." Yet that is exactly the attitude that many would have us adopt.

That proposition seems to me unreasonable. In my opinion, the chief criterion for deciding whether to include any given name in the list is the probable utility of that inclusion. The writer of an alleged unabridged dictionary is under an implied contract with the buyer to interpret to him not only language in its purity, but also colloquial, obsolescent, ill-formed, misleading and otherwise objectionable words, basing his decision as to including or excluding them chiefly on the consideration whether their inclusion will help enough readers and often enough to justify that inclusion. So, in accepting our commission we assumed a like duty toward readers and we should be governed by a like consideration.

Needless words will die a natural death; needed ones we cannot kill. The good we might do in hastening the death of the moribund by omitting them from this report is less than the good we do by teaching their meaning to those who will meet them in ante-mortem print. These readers have rights. We serve no class, but the whole.

Here we must remember that language, though nothing but man's tool, in the nature of the case must be a universal tool with all the defects common to universal tools. We must all use our mother tongue; and if confusion occurs when the poet uses words unknown to the smith and vice versa that is a necessary consequence of the universality of language.

Applying this principle to the present case, I cannot understand how there can be a shadow of a doubt about including troostite and sorbite. Not only do they occur very frequently in the writings of the best metallographists, but they represent substances of real importance. For certain industrial uses the troostitic state is invaluable; for others the sorbitic state is indispensable. The micrographer often needs "troostite" and "sorbite" to indicate what he sees. If they have already become convenient in this early stage of the development of heat treatment, how much more useful will they be hereafter?

When we come to osmondite the matter is less simple, because a smaller proportion of competent writers either use the name or believe that this additional stage in the transformation is of such importance as to justify giving it a special name.

Though I certainly cannot go so far as to say that this name is strongly needed, yet I am perfectly confident that the plain duty of the committee is to include it in its list. If I have no use for the color name "lavender," finding "violet," "lilac" and "slate color" quite sufficient, who am I that I shall forbid my neighbor to say "lavender" if he sees fit? Certainly the intermediate stages of the transformation have a present and prospective industrial importance so great that, when a writer of such weight and standing as the proposer of this name assures us that he finds need of further subdividing these stages and recognizing the osmonditic stage between troostite and sorbite, we can readily understand that he may be right, even if we personally have not felt the need of naming this stage. In view of the importance of his writings and of those of his followers, it is likely to be a convenience to a large number of readers to have the meaning of "osmondite" set forth in the committee's report. The help that would thus be given those readers certainly seems greater than any possible harm that can be done by recording and explaining the meaning of "osmondite." Hence it seems to be a duty to those readers to include and describe osmondite.

Thus the duty of the committee seems clear without certain other reasons of a different class which I am reluctant to invoke. For, though to some they seem of great force, indeed to be part of the general policy of "peace on earth, goodwill towards men," yet they seem opportunistic to others, and unfortunately these others are just the ones hardest to convince.

For instance, language is a convention, and the wishes as such of the parties in interest should be considered.

The propriety of its names is not in general dependent on any theory, now it is liable to be affected by later discoveries. The names are matters chiefly of taste and convenience, adopted as a matter of convenience and mutual agreement by those who have to use them.

Moreover, a committee should take care that it does not exercise its power arbitrarily, and for the gratification of the feelings of a majority of its members, remembering that, whereas little if any harm can be done by including a word which seems to us distasteful or needless, because nobody is forced thereby to use it; yet we may be mistaken in thinking it needless, and if the word is really needed, harm would be done by excluding it, not only through leaving readers occasionally in ignorance, but through defeating the whole plan for a uniform standard nomenclature.

Psychological considerations cannot be ignored. Personal and racial antagonisms, the odium metallurgicum, and other considerations, are here, and we need not shut our eyes to them. They should lead us to discount all pleas for excluding names, unless supported by cogent reasons.

Finally, as regards the nomenclature as a whole, the convenience of readers requires that the meanings of words should be changed as little as possible unless for strong reasons. In the present case this consideration is reinforced by two further ones, first that our whole knowledge of the life history of the substances to which these names apply is now most incomplete, and a great increase of it is to be looked for; and second that mineralogical nomenclature itself is not unlikely to receive a methodical readjustment. The time of that readjustment would be the proper time for readjusting metallographic nomenclature, so that the two may correspond.

For both these reasons it would seem wise to disturb the existing nomenclature as little as possible, and to confine our work to adjusting, rectifying and perfecting it, so that it may serve its present purpose.

Most of the present names have been in general use for nearly a quarter of a century; they are tools to which our hands are wonted. To attempt to wrench them from us and forbid their use would be as unwise as it would be futile. That sort of prohibition certainly would not prohibit.

Columbia University,
New York City.

Continuous Carbon Dioxide and Temperature Recorder.—In the article by Mr. Ed. A. Uehling, published in our December issue, page 656, there is a misprint in formula (5) on page. 657. The second term in the brackets should be $3.84Ha$ instead of $0.88Ha$.

Wage and Bonus Systems.—The Emerson Company, 30 Church Street, New York City, has just issued an interesting pamphlet, entitled "A Comparative Study of Wage and Bonus System." After a general introduction on the systems of paying for work on a basis of status or on a basis of contract or on a basis of individual effort, the characteristic features of bonus systems are explained. By means of simple diagrams the following systems of compensation are very clearly represented: time rate, piece rate, Halsey one-third bonus system, Halsey two-third bonus system, Rowan premium system, Taylor differential piece-rate system, Gantt bonus system and Emerson bonus system. The latter is described in some detail. The little pamphlet is well worth the attention of employers of labor.

Cyaniding by Continuous Decantation in Clear County, Colorado.

By H. C. Parmelee.

In the oldest mining district in Colorado, where the stamp, the amalgamating plate and the concentrating table have held sway for almost fifty years, some of the latest ideas in cyanide practice are in successful operation. One is not accustomed to think of cyanidation in connection with the silicious sulphide ores of Clear Creek county, although at intervals during the past five years several extensive experiments were carried out on a laboratory scale which indicated the amenability of many of those ores to that process. Higher recovery and greater profit were indicated in these tests as compared with former practice, but for one reason or another no commercial operations resulted.

FIG. 1. DECREASE IN KCN IN SANDS COMPARED ON WASHING SANDS WITH BARREN SOLUTION AND WITH WATER.

There are many difficulties to be overcome in an old district which do not obtain in a new one. Conservatism and skepticism combine to retard progress, making it difficult to procure money; and when these difficulties have been overcome, economy suggests the use of old mills and equipment as far as possible. These conditions limit the metallurgist and work a hardship on the industry in general for although the results show an improvement they are not the best that it would be possible to obtain with new, well-designed plants and modern equipment.

It has remained for the Hudson Reduction Company, Idaho Springs, Col., to treat successfully by amalgamation, concentration and cyanidation, the varied ores produced in that district. Experimental work was commenced about a year ago under the direction of Arthur H. Roller, manager, and Justin H. Haynes, metallurgist, and the present plant is the result of their preseverance under many adverse circumstances. An old twenty-stamp amalgamation-concentration mill has been remodeled to include cyanidation by continuous decantation in Dorr slime thickeners. Filtration is eliminated, excepting the use of clarifying leaves preceding precipitation of the cyanide solution. Warm solutions are used throughout the plant, being maintained at about 30° C. at the zinc boxes, and electrolytic oxygen is being experimented with as a means of keeping the solutions well oxidized.

The mill is operated on a custom basis, the ores being bought on a schedule based on their gross valuation. The ores are mainly silicious sulphides of iron, although some contain lead and copper, the latter metal averaging about 1 per cent in the mill heading. The ratio of silver to gold averages about 15:1. The great variety of ores offered for treatment, and the present lack of bedding facilities or bin room, make it impossible to depend on a uniform feed to the mill and demand close attention to the solutions. The average gross value of the ore is about $10 per ton, but the ratio of concentration in the different ores varies widely, as also does the presence of cyanicides and the percentage of slime formed. Notwithstanding these conditions, the average recovery is 88 per cent, which is probably 25 per cent higher than that of old practice in the district.

The addition of the cyanide process has not greatly altered the former percentages of recovery by amalgamation and concentration, but has converted a former tailing loss into additional saving. On $10 ore about $1 per ton, or 10 per cent, is recovered on the amalgamating plates. The percentage recovery by cyanide varies with the concentration ratio and the quantity of slime formed. With an ore of high concentration ratio perhaps 30 per cent of the total value is recovered in the concentrate and 50 per cent by cyanide, while the figures are practically reversed on an ore of low concentration ratio. Whether amalgamation and concentration would be retained as features of a new plant would have to be decided by experiment and would depend to a great extent on the available ores. Coarse gold would suggest amalgamation unless fine grinding could eliminate that step. Ores containing galena would require concentration. It is possible therefore that amalgamation might be dispensed with, although improbable that concentration could be entirely eliminated. At the Hudson mill the solubility of much of the gold and silver in cyanide solution is quite marked, about $1.50 in value going into solution in the batteries.

Sampling.

The sampling is well done, although at greater expense than would be necessary in a better arranged plant. The first reduction in size is to 1½ in., this product being elevated to a Vezin sampler where the first cut of 20 per cent is made, the reject going to the battery bins. The 20 per cent sample is then crushed to ¾-in. size, and again cut by a second Vezin machine giving 20 per cent, or 4 per cent of the entire lot. The final cut is then crushed to ⅜-in. size for coning and quartering, this operation resulting in a sample of 15 lb., which is ground and split on Jones riffles to about 1 lb. The final sample is then ground through 120-mesh screen.

Milling.

In these notes reference is made to the accompanying flowsheet and plates which represent graphically some details of treatment. The capacity of the plant has been increased from 60 tons to 88 tons per day since the flowsheet was drawn, but the figures given are proportionately correct. The plates, also, may not correspond exactly with the average figures given in the notes, for the conditions vary greatly from day to day, and the curves may represent conditions during a short period of time, while the figures given in the notes are averages over longer periods.

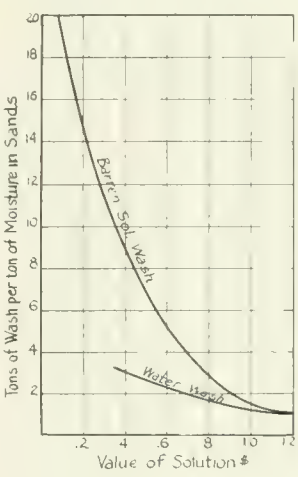

FIG. 2. DECREASE IN GOLD CONTENT IN SAND SOLUTION COMPARED ON WASHING SANDS WITH THE BARREN SOLUTION AND WITH WATER.

The ore is crushed in cyanide solution by twenty 850-lb. stamps, dropping ninety times per minute, with a height of drop of 6 in. Ton-cap screens are used equivalent to 12-mesh, giving a stamp duty of 4.4 tons per stamp per 24 hours. The plate area is 52 in. wide by 12 ft. long for each set of five stamps, and is arranged in three drops. Practically all of the amalgamation occurs on the uppermost section.

The pulp is immediately concentrated without classification on four tables as shown in the flowsheet. Four products are drawn from each table and combined. *Concentrate* is elevated to an Akins's classifier (not shown) and dewatered, for ship-

ment to the smelting plant. Experiment has shown that the concentrate can be cyanided separately from the gangue, and further tests will be made looking toward cyanidation of combined concentrate and slime. In this event all concentrates and middlings from tables would be reground and combined with the slime.

Middling from the four tables is then at once retreated on a fifth table making concentrate and coarse and fine tailing. The concentrate and fine tailing are combined with similar products from the first four tables, while the coarse tailing is reground in a 5-ft. grinding pan, 85 r.p.m. and combined with the slime. *Sand tailing* is pumped to an Akins classifier for separation of contained slime, and then washed by a large volume of barren solution to a dewatering table, from which it is discharged to waste. *Slime tailing* is the product from which the principal cyanide extraction is made. After being thickened in a Callow cone it passes by continuous decantation through the agitator and three Dorr continuous slime thickeners and thence to waste.

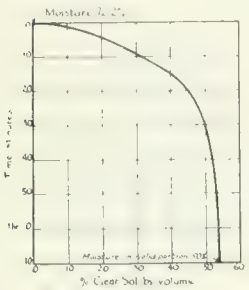

FIG. 3. SETTLEMENT OF SLIMES.

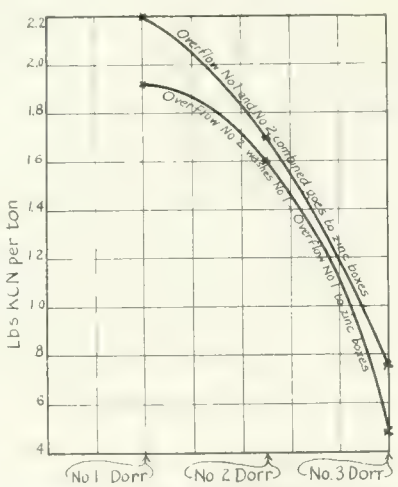
Sand Treatment.

It will be observed that the sand tailing is run to waste without cyanide treatment other than that received in its course through the batteries and on the tables. Under present conditions, at least, this is the best disposition to make of it. In fact, if the table feed were properly classified, and sufficient clear solution were available for table wash water, it is probable that the sand tailing would be so low in grade that it would not repay further treatment.

At present, as will be shown later, a part of the table wash water is slimy solution, and this fact, together with the lack of classification, allows the sand to carry more or less slime which largely gives it value.

From the Akins's classifier the sand is sluiced to the dewatering table with barren solution, used at the rate of 20 tons of barren solution per ton of solution in the sand. This washes the soluble gold and cyanide from the sand quite effectively. Experiments were made looking toward the use of water as a sand wash, but on account of the limited quantity which could be used without greatly increasing the mill solutions, it was found ineffective. The comparison of washing with barren solution and with water is show in Plates I and II. Water was more effective in washing out cyanide, but barren solution removed a greater value in gold and silver.



Lbs KCN per ton
Overflow No 3 and No 2 combined goes to 2 nine boxes
Overflow No 2 washes No 1 Overflow No 1 goes to nine boxes
No 1 Dorr
No 2 Dorr
No 3 Dorr

FIG. 4. DECREASE OF DISSOLVED CYANIDE IN DORR THICKENERS UNDER TWO SYSTEMS OF CONTINUOUS DECANTATION.

As used at the Hudson mill a concentrating table is very effective in dewatering sand tailing, an old Card table being used for this purpose. The discharge end is elevated 2 in. above the feed and a cleat nailed along the former to form a bank over which the tailing must discharge. The side pitch of the table is regulated according to the load so that no sand passes over the side with the slimy solution. The net result is that the tailing banks at the discharge end of the table and gradually passes over with an average of 14 per cent moisture. The most efficient dewatering done on the table has been 9 per cent moisture, and the poorest, 22 per cent; but a general average of 14 per cent has been maintained easily, at a capacity of 60 tons of sand in twenty-four hours. The sand tailing carries dissolved gold and silver to the value of $0.012 per ton, and has a gross value of $0.32 per ton.

Continuous Slime Treatment.

The following screen analyses, for one of which assay values also are given, show the grade of material treated by continuous decantation .

Mesh	%	Mesh	%	Value per ton.
— 80	7.3	— 80	8.7	$1.28
+ 100	5.9	+ 100	2.2	1.87
+ 150	2.4	+ 150	2.2	2.46
+ 200	3.8	+ 200	4.3	1.05
— 200	80.6	— 200	82.6	2.95

The high value of the minus 200-mesh product is believed to indicate the presence of brittle gold, and the fact that it remains undissolved at this stage of the treatment suggests that it may exist as a difficultly soluble alloy, especially in view of the fact that some gold dissolves so rapidly in the batteries. Plate III shows the results of a laboratory experiment on the settlement of slime from one of the ores treated.

The agitator is a cone-bottom tank 8 ft. in diameter and 24 ft. high, conforming practically to the proportions of a Pachuca tank. Air agitation may be used later, but at present the pulp is drawn from the bottom into a centrifugal pump and discharged downward on to a circular apron in the top of the tank. Thickened pulp from the Callow cone enters the agitator continuously and the discharge from the agitator to No. 1 Dorr thickener also is continuous. The discharge is delivered to the thickener by a launder which cuts a part of the stream flowing over the circular apron. This insures the transfer of a uniform sample of the agitator pulp into the decantation system. The quantity of pulp discharged from the agitator is regulated by a float rigidly connected with the pipe discharging on to the apron. As the float rises or falls it turns the mouth of the pipe slightly toward or away from the launder leading to the thickener, thereby increasing or decreasing the quantity passing out of the agitator.

No. 3 Dorr

FIG. 5. DECREASE OF DISSOLVED GOLD IN DORR THICKENERS UNDER TWO SYSTEMS OF CONTINUOUS DECANTATION.

The Dorr thickeners are each 16 ft. in diameter and 10 ft. deep, being of these dimensions in order to get them into the space available. All are equipped with spring drive gear. Nos. 1 and 2 make one revolution in ten minutes, and No. 3 one revolution in eleven minutes. The quantity of thickened underflow is regulated by the use of nozzles ranging from 5/16 to 9/16 in. in diameter. Ordinarily the tanks show clear solution to a depth of 4 ft. In the flowsheet twenty tons of slime is indicated as the usual load, but the machines occasionally carry from 50 to 60 tons of slime when certain ores are treated.

A difficulty encountered in the treatment of the ores received at this mill is the foaming of the solutions at various points in the plant, especially where the pulp flows into tanks, such as the Callow cone and the Dorr thickeners. This foaming becomes excessive in treating ore from a loose vein where a great deal of timbering is required, and in consequence of which an unusual amount of decayed wood becomes mixed with the ore. The foam is troublesome because it cannot be confined at any one place in the mill. In order to control its formation on the Callow cone and the Dorr tanks, a specially constructed feed box was placed on each machine. This consists simply of

FLOW SHEET, HUDSON REDUCTION CO., IDAHO SPRINGS, COLO.

an air-tight box extending 2 ft. below the surface of the solution, into which the feed pipe discharges and from which the foam formed therein may be continually siphoned through a pipe running to the sump from which the next thickener receives its feed. At the Hudson mill these boxes are made of wood and have not given perfect satisfaction on account of leakage. A better mode of construction would be to use a metal cylinder closed at one end, save for flanges to which the feed and siphon pipes could be attached.

The continuous counter-current flow of slime and solution through the Dorr thickeners is shown in the flowsheet. In general the slime flows from the agitator to No. 1, to No. 2, to

No. 3, being diluted and washed by solutions passing in the opposite direction. The clear overflow from No. 1 is precipitated after passing through ordinary clarifying leaves and the thickened underflow from No. 3 is discharged as slime tailing. Clear hot water is added as wash for the slime entering No 3

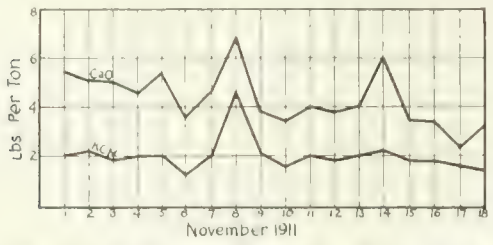

FIG. 6 DAILY CONSUMPTION OF KCN AND CaO PER TON OF ORE, FOR FIRST EIGHTEEN DAYS OF NOVEMBER, 1911

in sufficient quantity to provide for the solution lost in sand and slime tailings, thereby keeping the quantity of mill solution constant. The quantity of hot-water wash is regulated by a feather valve actuated by a float in the mill solution tank.

Prior to the adoption of the present flowsheet, in which the clear overflow of No. 2 Dorr is used to wash the pulp flowing into No. 1, the experiment was made of precipitating the overflow from both No. 2 and No. 1, instead of from No. 1 as shown. Plates IV and V show graphically the fall in cyanide and gold solution in the three machines under each system and clearly indicate the superiority of the present method.

The slime tailing has a gross value of $1.10 per ton, of which $0.12 per ton is dissolved gold and silver. Present conditions indicate the need of larger agitating capacity, inasmuch as gold and silver continue to go into solution even in No. 3 Dorr thickener from which the tailing is discharged. The value of the general mill tailing, slime and sand combined, is $0.78 per ton.

A study of the flowsheet will apparently show two cycles of mill solution. This is true only in a measure as they are connected at the mill solution tanks. One of the solutions is clear and the other slimy, this arrangement being necessary on account of lack of settling capacity to clarify all the solution. The cycle of clear solution is from No. 1 Dorr to the zinc boxes from which barren solution is used as wash water for the concentrating tables and the sand tailing, whence it ultimately flows back to the decantation system. The slimy solution is used in the batteries, also to a certain extent as part of the table wash water. From the overflow of the Callow cone and the Akins sand classifier the slimy solution is returned to the battery storage tank. When additional settling capacity is provided all the mill solutions will be clear, and an additional zinc box will be provided for precipitation of the present slimy solution, which is really too rich to be wasted.

Precipitation.

The zinc box has five compartments, each 30 in. x 30 in. x 30 in., giving a total capacity of 78.125 cu. ft. of zinc. Two hundred tons of solution are precipitated in twenty-four hours, being 2.56 tons of solution per cubic foot of zinc, or 3 tons per ton of ore treated. The boxes are constructed with 4-in. partitions and a 4-in. space beneath the ¼-in. mesh screen supporting the zinc. The value of the zinc box heading is about $1 per ton and of the tailing about 2 to 3 cents per ton. The temperature of the solution is maintained at about 30° C. at the zinc box, as it has been found that both solution and precipitation are more effective at this temperature than at the ordinary temperature of 15° C. A clean-up is made once a week, the precipitate being dried and screened through a ¼-in. mesh screen and shipped to the smelter refinery. Payment is made at the rate of 98 per cent of the silver, $20.15 per ounce for gold, with no treatment charge and no limit on the quantity of short zinc present.

The consumption of cyanide and lime varies from day to day with the different ores treated, as is shown in Plate VI, where the record is given for the first eighteen days of November, 1911. The average consumption of KCN is 2 lb. per ton of ore; CaO, 3 lb. per ton; Zn, 0.8 lb. per ton, and PbO, 0.5 lb per ton. The percentage alkalinity of the solution is standardized at the grinding pan, where the litharge also is added. The cyanide strength is standardized in a sump just preceding the mill solution storage.

In spite of all efforts made to keep the solution oxidized it carries reducing agents in considerable quantity. Even with the use of litharge in quantities of 1 lb. per ton of ore, the solution is not in desirable condition. Ten cubic centimeters of

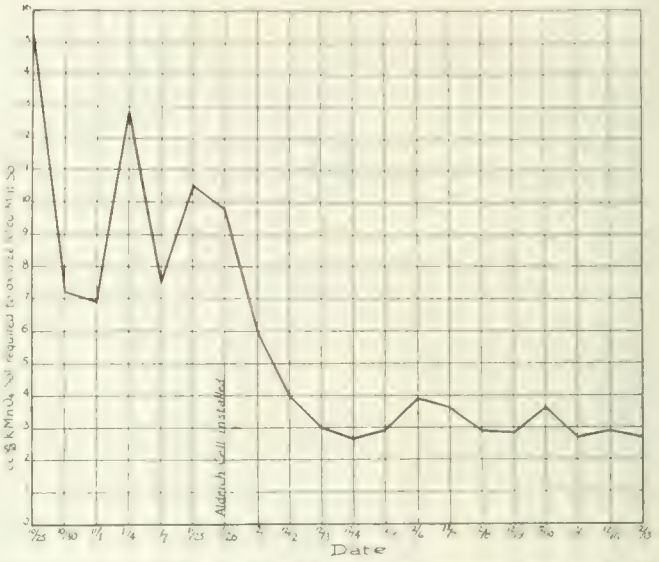

FIG. 7 EFFECT OF ELECTROLYTIC OXYGEN ON KEEPING CYANIDE SOLUTIONS FREE FROM REDUCING AGENTS

solution titrated boiling hot with tenth normal $KMnO_4$ solution requires from 6 to 15 c.c. to produce a permanent pink color. When these quantities of permanganate are plotted from day to day the reducing agents are seen to fluctuate widely. Mr. Haynes has recently started the experiment of using electrolytic oxygen to improve the solutions, following the suggestion of Mr. T. H. Aldrich, Jr., in a paper read before the San Francisco meeting of the A. I. M. E. The results obtained over the short time the experiment has been in effect are very encouraging, the quantity of permanganate required to give a permanent pink color to 10 c.c. mill solution having fallen to 2 c.c., as compared with 6 to 15 c.c. above, and the mill tailing also has fallen in value. Since the installation of this idea the permanganate consumption has fallen gradually and the plotting shows a steadily falling curve instead of the ragged line formerly obtained. Plate VII shows wide fluctuations in the reducing agents prior to the use of electrolytic oxygen and the steady fall and uniformly small quantity present after its adoption.

The electrolytic oxygen cell has been placed in the fifth compartment of the zinc box, where the barren solution will flow through it on its return to the mill. The cell is made up of 111 lead plates, 3.5 by 3 in. in area, alternate plates being connected to one pole of the current. The whole is contained in a hard-rubber box. The current used is 30 amp at 110 volts. If, as appears probable, this device will give highly oxidizing solutions, it may prove to be the solution of the problem of cyaniding concentrates in which reducing agents usually are present in large quantities.

Power and Labor.

The following tabulation gives the power required in the mill, the figures being taken from tests made when electricity

superseded steam. Two motors are in use, one 75 hp motor for the mill and one 15-hp motor for the sampler.

Machine.	Kw	Hp
Sampler	10.0	13.40
20 stamps	22.8	30.55
5 tables	1.6	2.14
Centrifugal pumps	18.4	24.66
44" Frenier pump, 12.5' lift, 50 tons sand, and 300 tons solution.	1.6	2.14
Dewatering table	1.2	1.61
Total	55.6	74.50

Three Dorr thickness and two Akin's classifiers not included.

In the mill two men are employed on each of three eight-hour shifts in addition to the foreman. On the day shift there is an extra man for repair work. In the sampler there are four men working one nine-hour shift.

Summary.

Average gross value of ore	$10.00 per ton
" " " " sand tailing	$0.32 per ton
" " " " slime tailing	$1.10 per ton
" " " " general tailing	$0.78 per ton
" percentage recovery	88%
Consumption of KCN	.2 lb per ton
" " CaO	.3 " " "
" " Zn	0.8 " " "
" " Pbo	0.5 " " "
Average value of zinc box heading	$1.00 per ton
" " " " " tailing	2 to 3 cents per ton
Tons solution precipitated per cu. ft. zinc	2.56
" " " " ton of ore	3.

The proportions of solution to ore and the percentage alkalinity (P A) and cyanide strength are given at various points on the flowsheet (page 29).

All things considered the work at the Hudson mill is most commendable. The management has proceeded carefully, making many investigations to prove the wisdom of each feature before adopting it, and the thoroughness of the experimental work is a warrant of the ultimate success of the methods employed.

The entire Clear Creek district must be indebted to those in charge of the work for pointing the way to better metallurgy and for their courtesy in making public the details here given. Perhaps further investigation will show that cyanidation has a wider application in the district than is now known and the remodeled Hudson mill may prove to be only the first of other cyanide plants to add to the recovery of the precious metals from Clear Creek County ores.

Calculations of Vacuum Pans.

By B. VIOLA, M. E.,
Member American Society of Mechanical Engineers.

In the evaporation of liquids the main problem is: how can we evaporate the greatest quantity with the least heating surface? Naturally the selection of the most economical medium of a heating surface is the most important matter of this subject. By describing the different evaporators and vacuum pans (this journal, Vol. IX. pp. 206, 251, 306, 349, 389) I have demonstrated the most practical and efficient heating surfaces, and now I wish to describe briefly how to figure the heating surface for the evaporation of given quantities of liquors.

As already mentioned, the materials chiefly employed for heating surfaces are copper, iron, and lead, or in combination copper with lead lining. Lately enameled iron is also used with good success.

Before we go further it is very important to give the heat transmission capacities of these materials. From the experiments of Molier, Ser, Joule, Hagemann, Jelinek, etc., Hausbrand reached the conclusion that the empirical formula

$$K_v = \frac{1900}{\sqrt{dl}} \qquad (1)$$

expresses the coefficient of transmission of heat between steam and boiling water in calories per square meter and hour and per degree C. temperature difference, using cylindrical copper pipes for circulating the steam inside and the water to be evaporated outside, where d is the diameter of the heating pipe in meters and l the length in meters.

This transmission coefficient can be taken for wrought-iron pipes 0.75 time the above value (1) for copper pipes, for cast-iron pipes 0.5 time value (1) and for lead pipes 0.45 time value (1). In practice, however, it is advisable to use only two-thirds of these values. If the solution has a strength of 10 to 25 per cent, this cofficient has to be reduced further by 20 or 30 per cent.

Single Effect.

Now, in order to find how much water can be evaporated by a certain heating surface per minute, I will commence with a single effect, 2 atmospheres absolute pressure, corresponding to a temperature of the heating steam of 120° C.

We suppose that a certain liquor enters the effect at a temperature of 45° C. from the juice heater and by the influence of vacuum pump and condenser we get an absolute pressure of 149 mm. corresponding to a vacuum of 611 mm. (24 in.) and a boiling point of 60° C.

Now we call:

t_0 = temperature of the liquor entering into the evaporator.

t_1 = boiling point of this liquor in the evaporator.

t_2 = temperature of the heating steam.

C = heat transmission coefficient, in calories per square meter per minute and 1° C. temperature difference $t_2 - t_1$.

H = heating surface of the apparatus in square meters.

Q = quantity of heat required in calories per minute.

$$Q = HC(t_2 - t_1) \qquad (2)$$

being the heat set free by condensation of the heating steam and passing through the walls into the boiling liquor.

Q_t = total heat. According to Regnault, to change one kilogram of water at 0° C. into saturated steam at the temperature t_2, there are required $606.5 + 0.305\ t_2$ calories.

Q_l = latent heat which is given off by condensation in the heating coils, according to Regnault, $= 606.5 - 0.695 t_2$ calories.

W_s = weight of the steam condensed in the heating tubes, in kilograms.

W_w = weight of the water evaporated by the heating surface.

Now let us consider copper coils of 75 mm. diameter and 20 meter lengths (in this case two coils where the inner coil has a smaller diameter than the outer coil), then according to formula (1)

$$K_v = \frac{1900}{\sqrt{dl}} = 1545$$

For practical use we take only two-thirds of this or 1030 and reducing it further in consideration of the dissolved substance by 20 per cent we get 824 calories per square meter per hour, which will give C = 13.73 calories per minute. The heating surface of the two coils, not taking the small thickness of the copper into consideration, will be approximately 10 square meters. We now have

$$Q = W_s Q_l \qquad (3)$$

$$W_s = Q \div Q_l \qquad (4)$$

$$Q = W_w (Q_l - t_0) \qquad (5)$$

$$W_w = Q \div (Q_l - t_0) \qquad (6)$$

Since $t_0 = 45$° C., $t_1 = 60$° C., $t_2 = 120$° C., $t_2 - t_1 = 60$° C., H = 10 sq. meters and C = 13.73 calories per minute, we find $Q = 10 \times 13.73 \times 60 = 8238$ calories per sq. meter and minute.

$$W_s = \frac{8238}{606.5 - (0.695 \times 120)} = 15.74 \text{ kgr.}$$

$$W_w = \frac{8238}{606.5 + (0.305 \times 60) - 45} = 14.21 \text{ kgr.}$$

We see from the above results that in a single effect having 10 square meters heating surface 14.21 kgr. of water can be evaporated per minute, if the liquor enters at 45° C. To

evaporate this quantity, 1574 kgr. of steam are necessary, or 1 kgr. of heating steam evaporates 0.90 kgr. water per minute, as the heat of the condensed steam given off through the walls is the evaporating power for the liquor surrounding the heating tubes.

For the evaporation of acids, mostly single effects are used and the heating coils are lead or lead-lined copper coils.

When using lead heating tubes, the heat transmission coefficient is only about 45 per cent of the value for copper tubes, or C = 5.79 calories per minute. Then we get

$$Q = 10 \cdot 5.79 \cdot 60 = 3474 \text{ calories.}$$

$$W_s = \frac{3474}{606.5 - (0.605 \cdot 120)} = 6.64 \text{ kgr.}$$

$$W_w = \frac{3474}{606.5 - (0.305 \cdot 60) - 45} = 5.99 \text{ kgr.}$$

so that 10 square meter lead heating surface will evaporate under the same conditions only 5.99 kgr. water from the liquid per minute, and that to accomplish this 6.64 kgr. of heating steam are necessary.

Now let us suppose that a certain quantity of acid liquors has to be evaporated and the size and the heating surface of the single effect has to be calculated, then we can do this by the following method.

First of all, of course, the quantity of the liquor, the density of the thin liquor and the density of the concentrated liquor must be given.

Design of Tartaric Acid Evaporator.

In our case we will assume 1000 kgr. tartaric acid liquor which has a density of 9.1° Beaumé and has to be concentrated to 35° Beaumé. Tartaric acid liquor contains at 9.1° Beaumé 14 per cent solids and at 35° Beaumé 57.9 per cent solids. The specific heat, which we will need later on, is 0.911 at 9.1° Beaumé and at 18° C. according to Julius Thomsen, 18° C. = 0.911 and from his results we find the specific heat for 35° Beaumé to be 0.668.

The water to be evaporated can be found by the following formula:

$$W_w - W_c = W_w \left(1 - \frac{d_1}{d_2}\right) \qquad (7)$$

Where

W_w = the weight of the liquor to be concentrated = 1000 kg.

W_c = the weight of the concentrated liquor.

d_1 = percentage of solids in W_w = 14 per cent,

d_2 = percentage of solids in W_c = 57.9 per cent, therefore

$$W_w - W_c = 1000 \left(1 - \frac{14}{57.9}\right) = 760 \text{ kg. of water.}$$

We have to find now the quantity of calories needed to evaporate 760 kgr. of water from the following formula:

$$Q = W_w C_t + W_c S_1 t_1 - W_w S_0 t_0 \qquad (8)$$

Where

C_t = total heat, according to Regnault = 606.5 + 0.305t.

S_0 = specific heat of the thin liquor = 0.911.

S_1 = specific heat of the concentrated liquor = 0.668.

t_0 = temperature of the thin liquor in degrees C. = 45°

t_1 = boiling temperature of the liquor in degrees C. = 60°

Inserting the numerical values in equation (8) we get Q = 614,266 calories.

To obtain the heating surface H for this single effect we can use the following formula, which follows directly from equation (2):

$$H = \frac{Q}{C (t_2 - t_1)} \qquad (9)$$

Where

Q = the heat passing through the heating surface in calories.

C = the heat transmission coefficient per square meter and hour = 1545 × 0.3 = 463.5 calories (1545 being the heat transmission coefficient for copper tubes and 0.3 the reduction factor for lead-copper tubes).

t_2 = temperature of the heating steam = 120° C.

t_1 = temperature of the boiling liquor = 60° C.

$$H = \frac{614{,}266}{463.5 \cdot (120 - 60)} = 22.08 \text{ square meters.}$$

If lead-lined copper tubes are used for heating coils, which are very advantageous, as they have a larger heat transmission coefficient than lead alone, we can take the heat transmission coefficient that of copper and lead combined.

Design of Quadruple Effect.

I will now take up the calculation of a multiple effect, say a quadruple effect. I will fix the size of the heating surface of the first body, and accordingly find the heating surfaces of the second third and fourth bodies. In this case I will first give a general solution and then reduce the heat transmission coefficient to say 25 per cent to take account of the dissolved substances in the liquor.

In designing an evaporator, the most important question is as to the design which will be able to evaporate the most water with the least quantity of steam.

The cheapest steam is always the exhaust steam from the engine or pumps, assuming, of course, that a steady supply and pressure can be relied upon.

The exhaust steam economically discharged from any engine has about 0.5 atmosphere pressure, corresponding to a temperature of 112° C. The liquor in the first body with this heating steam is boiling at 99° C. and gives off steam of the same temperature for heating the second body. The liquor boils there at 86° C. and gives off steam of the same temperature for the heating of the third body, where the liquor boils at 73° C. Vapors of the same temperature pass over into the fourth body and cause boiling at 60° C.

The temperature difference between the heating steam of 112° C. and the boiling point of the fourth body is 52° C. To get an equal temperature difference in the four bodies we divide the 52° C. by four and get 13° C. as the difference in the temperature for each body.

The vacuum in the four bodies according to their respective boiling points will be the following:

	Boiling point.	Vacuum.
First body	99° C.	116 mm
Second body	86° C.	322 mm
Third body	73° C.	484 mm
Fourth body	60° C.	611 mm

By selecting an evaporator for the first body containing one hundred 50-mm diameter copper tubes, 4 meters long each, we have a heating surface of 68 square meters. The second, third and fourth bodies will be found by calculation.

The heat transmission coefficient for the size of copper tube equals 4253 calories per square meter and hour for 1° C., but for liquors containing about 25 per cent dissolved substances only one-half of the above coefficient can be assumed. We further suppose that the liquor to be evaporated enters the first body at a temperature of 45° C. The calculations are then as follows:

First Body.

t_0 = 45° C. (temperature of entering liquor).

t_1 = 99° C. (boiling temperature).

t_2 = 112° C. (temperature of heating steam).

$t_2 - t_1 = 112 - 99 = 13°$ C. (temperature difference).

H_1 = 68 square meters (heating surface).

$C = \frac{4253}{2} = 2126.5$ calories (heat transmission coefficient).

$Q_1 = H_1 C (t_2 - t_1)$ = quantity of calories passing through the heating surface = 68 × 2126.5 × 13 = 1,879,826 calories.

$Q_{t_1} = 606.5 - 0.605t_1 - 0.00002t_1^2 - 0.0000003t_1^3 = 528$ cal

$Q_{t_1} = 606.5 + 0.305\ t_1 = 630.60.$

$Q_{t_1} - t_0 = 606.5 + (0.305 \times 99) - 45 = 591.69.$

$$W_{s1} = \frac{Q_1}{Q_{t_1}} = \frac{1,879,826}{528} = 3560.29 \text{ kgr. condensed steam.}$$

$$W_{w1} = \frac{Q_1}{Q_{t_1} - t_0} = \frac{1,879,826}{591.69} = 3177.04 \text{ kgr. evaporated water.}$$

Second Body.

$t_0 = 99°$ C.

$t_1 = 99 - 13 = 86°$ C.

$t_2 = 99°$ C.

$t_2 - t_1 = 13°$ C.

$Q_{t_2} = 606.5 - 0.695t_2 - 0.00002t^2_2 - 0.0000003t^3_2 = 537.2$ cal.

$Q_{t_2} - t_0 = 606.5 + (0.305 \times 86) - 99 = 533.73$ calories.

$Q_2 = W_{w1} Q_{t_2} = 3177.04 \times 537.2 = 1,706,705.88$ calories.

$$H_2 = \frac{1,706,705.88}{2126.5 \times 13} = 61.73 \text{ square meters.}$$

$W_{s2} = 3177.04$ kgr. condensed steam.

$$W_{w2} = \frac{1,706,705.88}{533.73} = 3197.69 \text{ kgr. evaporated water.}$$

Third Body.

$t_0 = 86°$ C.

$t_1 = 86 - 13 = 73°$ C.

$t_2 = 86°$ C.

$t_2 - t_1 = 13°$ C.

$Q_{t_3} = 606.5 - 0.695t_2 - 0.00002t^2_2 - 0.0000003t^3_2 = 540.39.$

$Q_{t_3} - t_0 = 606.5 + (0.305 \times 73) - 86 = 542.7$ calories.

$Q_3 = W_{w2} Q_{t_3} = 3197.69 \times 546.39 = 1,746,785.84$ calories.

$$H_3 = \frac{1,746,785.84}{2126.5 \times 13} = 63.18 \text{ square meters.}$$

$W_{s3} = 3197.69$ kgr. condensed steam.

$$W_{w3} = \frac{1,746,785.84}{542.76} = 3218.33 \text{ kgr. evaporated water.}$$

Fourth Body.

$t_0 = 73°$ C.

$t_1 = 60°$ C.

$t_2 = 73°$ C.

$t_2 - t_1 = 13°$ C.

$Q_{t_4} = 606.5 - 0.695t_2 - 0.00002t^2_2 - 0.0000003t^3_2 = 555.54$ cal.

$Q_{t_4} - t_0 = 606.5 + (0.305 \times 60) - 73 = 551.8$ calories.

$Q_4 = W_{w3} Q_{t_4} = 3218.33 \times 555.54 = 1,787,911$ calories.

$$H_4 = \frac{1,787,911}{2126.5 \times 13} = 64.67 \text{ square meters.}$$

$W_{s4} = 3218.33$ kgr. condensed steam.

$$W_{w4} = \frac{1,787,911}{551.8} = 3240 \text{ kgr. evaporated water.}$$

To summarize the results, we have found:

Body	Heat units in calories	Heating surface in square meters	Condensed steam in kgrs.	Evaporated water in kgrs.
1.....	1,879,826.00	68.00	3,560.27	3,177.04
2.....	1,706,705.88	61.73	3,177.04	3,197.69
3.....	1,746,785.84	63.18	3,197.69	3,218.33
4.....	1,787,911.00	64.67	3,218.33	3,240.00
	7,121,228.72	257.58	13,153.33	12,833.06

In this quadruple effect 12,833.06 kgr. water can be evaporated from the thin liquor per hour with a heating surface of 257.08 square meters, or 49.82 kgr. per square meter per hour.

To evaporate this quantity 3560.27 kgr. steam have to be utilized in the first body, consequently one kilogram of steam can evaporate 3.5 kilograms of water.

In the above outline, giving the general calculations, we did not take into consideration the heat radiated from the surfaces of the different effects which cannot be prevented entirely if even some covering is used.

The so-called self evaporation was also neglected, which goes on in the second, third, and fourth bodies. When the heating steam and liquor enter the second body from the first body, they have the same temperature, but, on account of the higher vacuum there, the liquor will naturally boil at a lower temperature. The liquor has the boiling temperature of the first body, consequently it drops here to the temperature of the lower boiling point, under a higher vacuum, and gives off the difference of the heat which helps the evaporation. Or, in other words, it evaporates itself to a certain degree and this we call *self-evaporation.*

As it is well known, the theoretical results always need some corrections, and so we would advise to correct the calculated heating surfaces for the different bodies, taking the circumstances of the case into proper consideration. By an increase of about 25 per cent or more in a similar case, for the different bodies we will get a result on which we surely can rely as satisfactory when designing the quadruple effect.

Design of Quadruple Effect for Recovery of Potash from Wool Waste Liquor.

We will now consider another case in which a certain quantity of liquor is given and all the data of a quadruple effect have to be calculated. It has to handle 50,000 kgr. wool waste liquor (from the wool washing process) for the purpose of the recovery of potash, which is well worth recovering.

This liquor contains the following constituents or solids dissolved:

Potassium carbonate (K_2CO_3)....	1.63	per cent
Potassium chloride (K Cl).....	0.18	per cent
Potassium sulphate (K_2SO_4).....	0.236	per cent
Sodium carbonate ($NaCO_3$).....	0.129	per cent
Grease	0.249	per cent
Organic impurities.....	0.696	per cent
Insoluble matters.....	0.15	per cent
	3.27	per cent

It has a density of 3.70° Baumé.

This liquor should be evaporated to 40.8° Baumé so as to contain:

Potassium carbonate.....	28.60	per cent
Potassium chloride.....	3.15	per cent
Potassium sulphate.....	4.13	per cent
Sodium carbonate.....	2.26	per cent
Grease	4.38	per cent
Organic impurities.....	12.22	per cent
Insoluble matters.....	2.64	per cent
	57.38	per cent

Hence from these 50,000 kgrs. of liquor we have to evaporate

$$W_w = W\left(1 - \frac{D_1}{D_4}\right)$$

$$50,000\left(1 - \frac{3.27}{57.38}\right) = 47,155 \text{ kgr. water}$$

where

W_w = weight of the evaporated water.

W = weight of the thin liquor.

D_1 = density of the thin liquor.

D_4 = density of the concentrated liquor.

So that the weight of the concentrated liquor becomes

$$W_c = W - W_w \qquad (11)$$

$$= 50,000 - 47,155 = 2845 \text{ kgrs.}$$

Before going further in the calculation we have to decide on the pressure differences in the different bodies. Although some authorities state that the fall of the temperature between the heating chamber and juice spaces of the different

bodies must be constant, yet it will be shown that it must not be so in order to get the right results.

We will make the difference of pressure in the different bodies constant. We suppose that the liquor boils in the first body at 100° C. and in the fourth body at 60° C., then the total difference will be

$$1.00 - 0.196 = 0.804 \text{ atm}$$

Therefore the pressure difference in each body will be: 0.804 ÷ 3 = 0.268 atmosphere, and the pressure will be in the

First body		1.00	atmosphere
Second body	1.00 — 0.268 =	0.732	"
Third body	0.732 — 0.268 =	0.464	"
Fourth body	0.464 — 0.268 =	0.196	"

According to these pressures the boiling points and vacuums in the different bodies will be as follows:

	1 Body	2 Body	3 Body	4 Body
Pressure	1 atm.	0.732 atm.	0.464 atm.	0.196 atm.
Temperature	100° C.	90.27° C.	79.65° C.	60° C.
Vacuum	0	233.84 mm	407.12 mm	611.21 mm

Quantities of Water to Be Evaporated in the Different Bodies.

To evaporate the 47,155 kgrs. water from the 50,000 kgr. thin liquor so as to increase the density from 3.27 per cent to 57.38 per cent, according to Hausbrand the total quantity evaporated in the fourth body of a quadruple effect is 0.284 of the total evaporation

$$= 0.284\ (50{,}000 - 2845)$$
$$= 47{,}155 \times 0.284 = 13{,}392.02 \text{ kgr.}$$

With this data we will now figure the probable quantities evaporated in the other bodies, using Regnault's formulas:

C_t = total heat = $606.5 + 0.305t$.

C_l = latent heat = $606.5 - 0.695t - 0.00002t^2 - 0.0000003t^3$.

C_s = sensible heat = $t + 0.00002t^2 + 0.0000003t^3$.

Consequently

	1 Body.	2 Body.	3 Body.	4 Body.
Temperature	100° C.	90.27° C.	79.65° C.	60° C.
Total heat	637.0	634.03	630.79	624.8
Latent heat	536.5	543.38	550.87	504.7
Sensible heat	100.5	90.65	79.92	60.13

Having determined the basis for the quantity of water to be evaporated in the fourth body, we can start to calculate the third body.

It is plain that the sum of the heat in the concentrated liquor leaving the fourth body, and the vapor passing into the condenser and of the condensed water leaving the heating chamber, must be equivalent to the heat of the liquor leaving the third body and the heat of the evaporated water entering as vapor the heating chamber of the fourth body.

Following Francis Maxwell we can write now the following formula:

$$(W_{w4} + W_c)\, S_{h3} t_3 + W_{w3} C_{t3} = W_c S_{h4} t_4 + W_{w4} C_{t4} + W_{w3} C_{s3}$$

where

W_w = weight of the evaporated water in each individual body.

W_c = weight of the concentrated liquor.

S_h = specific heat of the liquor.

t = the boiling point in the bodies in degrees C.

C_t = total heat of vapor in calories.

C_s = sensible heat of condensed steam in calories.

C_l = latent heat of vapor in calories.

From our former calculations we see that the total heat of the evaporated water of the third body, forming the heating vapor of the fourth body ($W_{w3} C_{t3}$) less the sensible heat of this, condensed to water in the heating chamber of the fourth body ($W_{w3} C_{s3}$) must be the latent heat of the heating vapor in the fourth body ($W_{w3} C_{l3}$). Hence, from the above formula

$$W_{w3} C_{l3} = W_{w4} C_{t4} + W_c S_{h4} t_4 - (W_{w4} + W_c)\, S_{h3} t_3$$
$$W_{w3} C_{l3} + W_c S_{h4} t_4 - (W_{w4} + W_c)\, S_{h3} t_3$$
$$W_{w3} = \frac{W_{w3} C_{l3} + W_c S_{h4} t_4 - (W_{w4} + W_c)\, S_{h3} t_3}{C_{l3}} \qquad (12)$$

S_{h3}, S_{h3} and W_{w3} must now be found, where S_h = the specific heat. The specific heat of any solution can be found from the sum of the specific heats of the water and the dry substance it contains:

$$S_h = \frac{(100 - D)\, C_s}{100\, t} + \frac{S_d D}{100} \qquad (13)$$

D = percentage of dry substance.

C_s = sensible heat of water in calories.

S_d = specific heat of dry substance.

t = temperature of boiling in degrees C.

In our case the specific heats of the dry potash compounds in the wool waste-liquors are the following:*

1 Body.	2 Body.	3 Body.	4 Body.
100° C.	90.27° C.	79.65° C.	60° C.
at			
0.28237	0.28106	0.2797	0.2772

Using the above formula to determine the specific heat of the liquor in the fourth body, we get

$$S_{h4} = \frac{(100 - D_4)\, C_{s4} + S_{d4} D_4 t_4}{100\, t_4} \qquad (14)$$
$$= 0.5862 \text{ calorie.}$$

To figure S_{h3} it is necessary to obtain the density of the liquor leaving the third body, which is, according to the formula,

$$D_3 = \frac{W D_1}{W_{w4} + W_c} \qquad (15)$$
$$\frac{163{,}500}{16{,}237} = 10.07 \text{ per cent} = 11.57° \text{ Baumé.}$$

From this we get the specific heat like before

$$S_{h3} = \frac{(100 - D_3)\, C_{s3} + S_{d3} D_3 t_3}{100\, t_3} \qquad (16)$$

in which $S_{d3} = 0.2797$, hence $S_{h3} = 0.9305$ calorie.

Now we can calculate the value of W_{w3}, inserting the numerical values found in equation (12)

$$W_{w3} = 13{,}186 \text{ kgr.}$$

In passing over to the evaporation in the second body, we have first to determine the density of the liquor leaving this body:

$$D_2 = \frac{W D_1}{W_{w4} - W_{w3} - W_c} \qquad (17)$$
$$= \frac{163{,}500}{29{,}423} = 5.55 \text{ per cent} = 6.36° \text{ Bé.}$$

The specific heat now is

$$S_{h2} = \frac{(100 - D_2)\, C_{s2} + S_{d2} D_2 t_2}{100\, t_2} \qquad (18)$$
$$= 0.96407 \text{ calorie.}$$

The evaporated water in the second body can be calculated by using the methods and different formulas of our first example for a quadruple effect. Thus the sum of the heat contained by the liquor entering the third body $(W_{w4} + W_{w3} + W_c)\, S_{h2} t_2$ and the heat of the vapors passing into the third body $(W_{w2} C_{t2})$ must equal the sum of the heat of the liquor leaving the third body $(W_{w4} + W_c)\, S_{h3} t_3$ and the heat and vapor leaving the third body $(W_{w3} t_3)$, and the heat of the condensed heating steam $(W_{w2} C_{s2})$ leaving the third body.

$$(W_{w4} - W_{w3} + W_c)\, S_{h2} t_2 + W_{w2} C_{t2} = (W_{w4} + W_c)\, S_{h3} t_3 + W_{w3} t_3 + W_{w2} C_{s2}$$
$$W_{w2} C_{t2} - W_{w2} C_{s2} = (W_{w4} + W_c)\, S_{h3} t_3 + W_{w3} C_{t3} - (W_{w4} + W_{w3} + W_c)\, C_{h2} t_2$$
$$W_{w2} C_{t2} - W_{w2} C_{s2} = W_{w2} (C_{t2} - C_{s2}) = W_{w2} C_{l2}$$
$$W_{w2} C_{l2} = (W_{w4} + W_c)\, S_{h3} t_3 - (W_{w4} + W_{w3} + W_c)\, C_{h2} t_2$$

*For all the analytical and thermo-chemical data the author is indebted to Dr. Walter Glaeser, chemist of Chas. Pfizer & Co., Chemical Works, Brooklyn.

$$W_{w2} = \frac{(W_{w4} + W_{w3}) S_{h3} t_3 + W_w C_{t_1} - (W_{w4} + W_{w3} + W_{w2}) S_{h2} t_2}{C_{t_2}} \quad (19)$$

Hence by substituting the numericals values, we get

$$W_{w2} = 12{,}809 \text{ kgr.}$$

Now we can pass over to the first body, but have first to determine the density of the liquor leaving it:

$$D_1^1 = \frac{W D_1}{W_{w4} + W_{w3} + W_{w2} + W_c} \quad (20)$$

$$= 3.87 \text{ per cent} = 4.5^\circ \text{ Baumé.}$$

$$S_{h_1} = \frac{(100 - D_1^1) C_{s1} + S_{d1} D_1^1 t_1}{100 t_1} \quad (21)$$

$$= 0.977 \text{ calorie.}$$

We can use for the quantity of evaporation the same formula which was used for the second body:

$$W_{w1} = \frac{W_{w2} C_{t_2} - (W_{w4} + W_{w3} + W_{w2} + W_c) S_{h2} t_2 - (W_{w4} + W_{w3} + W_{w2} + W_c) S_{h1} t_1}{C_{t_1}} \quad (22)$$

$$= 12{,}406 \text{ kgr.}$$

Summarizing the above results for the different bodies, we have:

1 Body	12,406 kgr.
2 Body	12,809 kgr.
3 Body	13,186 kgr.
4 Body	13,912 kgr.
	52,313 kgr.

which would mean the evaporation of more water from our liquor than it contains. However, we can make a correction, reducing the quantities for the four bodies in the same proportion, which is practically permissible. In this case by deducting 9.85 per cent the above results are reduced as follows:

1 Body 12,406 — 9.85 per cent = 11,184 kgr. water evaporated.
2 Body 12,809 — 9.85 per cent = 11,547 kgr. water evaporated.
3 Body 13,186 — 9.85 per cent = 11,887 kgr. water evaporated.
4 Body 13,912 — 9.85 per cent = 12,541 kgr. water evaporated.

47,159 kgr.

which nearly equals the total weight of the water to be evaporated. From these results we can figure the heat consumption for each body.

But before doing so, it is important to consider the loss of heat from the bodies and their pipe connections by radiation and by the contact with the surrounding air.

Radiation and Connection Heat Losses.

For our example we are going to use wrought-iron evaporating bodies 5 meters long and 3 meters diameter each. The exposed surfaces we will figure as 65 square meters for each body.

According to Peclet those losses are expressed in the following formula:

$$M = R + A \quad (23)$$

where M is the total loss of heat per hour and per square meter in calories, R the loss by radiation and A the loss to the surrounding air. Peclet's empirical formulas are:

$R = 124.72 \, K \, a \, \Theta \, (a^t - 1)$, where

Θ = temperature of the air,

t = difference in temperature between the hot body and the air,

$a = 1.0077$, and for wrought iron,

$K = 2.77$;

further $A = 0.552 \, K_1 \, t^{1.233}$ and in our case

$K_1 = 2.13$.

Substituting the numerical values, we get

$$M = R + A = 124.72 \, K \, a \, \Theta \, (a^t - 1) + 0.552 \, K_1 \, t^{1.233} \quad (24)$$

According to this formula we find the following results for our case in Peclet's table:

For the first body with 70° C. temperature difference between the body and the surrounding air:

$M_1 = 221 + 213 = 434$ calories per square meter.

The exposed surface being 65 square meters, the total loss L_1 is

$L_1 = 65 \times 434 = 28{,}210$ calories.

$M_2 = 183 + 176.3 = 359.3$ calories per square meter.

$L_2 = 359.3 \times 65 = 23{,}354.5$ calories.

$M_3 = 146 + 140.5 = 286.5$ calories per square meter.

$L_3 = 286.5 \times 65 = 18{,}622.5$ calories.

$M_4 = 76.7 + 75 = 151.7$ calories per square meter.

$L_4 = 151.7 \times 65 = 9860.5$ calories.

Heat Consumption of Different Bodies.

We can now proceed to find the total heat consumption for each body by calculating the utilized heat. The total amount of heat of a certain liquor in a certain body is equal to the heat contained by this liquor and the heat which is utilized to reach a certain evaporation.

For the first body of this quadruple effect this will be as follows:

$$W_{w1} C_{t_1} + (W_{w4} + W_{w3} + W_{w2} + W_c) S_{h1} t_1 = W_w S_{h0} t_0 + Q_{u1}$$

where

Q_{u1} = utilized heat in first body in calories.

S_{h0} = specific heat of the entering liquor in the first body.

t_0 = temperature = 80° C. entering liquor in the first body.

$$Q_{u1} = W_{w1} C_{t1} + (W_{w4} + W_{w3} + W_{w2} + W_c) S_{h1} t_1 - W_w S_{h0} t_0 \quad (25)$$

$$S_{h0} = \frac{(100 - D_0) C_{s0} + S_{d0} D_0 t_0}{100 t_0} \quad (26)$$

$$= 0.979 \text{ calorie.}$$

By inserting the numerical values in (25) we now get

$$Q_{u1} = 7{,}000{,}922 \text{ calories.}$$

and the total heat consumption for the first body: Q^1

$$Q^1 = Q_{u1} + L_1 \quad (27)$$

$$= 7{,}000{,}922 + 28{,}210$$

$$= 7{,}029{,}132 \text{ calories per hour.}$$

The total heat consumption for the next bodies can be calculated similarly as we did it in our first example of the quadruple effect, namely by multiplying the vapor of the preceding body with the corresponding latent heat, and adding to it the corresponding losses by radiation as found before.

$$Q_{u2} = 11{,}184 \times 536.5 = 6{,}000{,}216$$

$$Q^{II} = Q_{u2} + L_2 \quad (28)$$

$$= 6{,}023{,}570.5 \text{ calories per hour.}$$

$$Q_{u3} = 11{,}547 \times 543.38 = 6{,}274{,}408.86.$$

$$Q^{III} = Q_{u3} + L_3 \quad (29)$$

$$= 6{,}293{,}031.36 \text{ calories per hour.}$$

$$Q_{u4} = 11{,}887 \times 550.87 = 6{,}548{,}191.69.$$

$$Q^{IV} = Q_{u4} + L_4 \quad (30)$$

$$= 6{,}558{,}052.19 \text{ calories per hour.}$$

The total heat consumption of the different bodies is, therefore, as follows:

First body	Q^I	= 7,029,132 calories
Second body	Q^{II}	= 6,023,571 calories
Third body	Q^{III}	= 6,293,031 calories
Fourth body	Q^{IV}	= 6,558,052 calories

Self-Evaporation.

Self-evaporation has already been mentioned, and in this case we will consider it and the resulting heat-unts will have to be deducted from the total heat consumption of the second, third, and fourth bodies.

Self-evaporation for the second body:

$$W_{e2} = (W - W_{w1}) (t_1 - t_2) S_{h1} \quad (31)$$

Where

$W - W_{w1}$ = the liquor leaving the first body,

$t_1 - t_2$ = temperature difference between the first and second bodies.

$W_{s_2} = (50{,}000 - 11{,}184)(100 - 90.27) \times 0.977$
$= 368{,}752$ calories.

$W_{s_3} = (W - W_{w_1} - W_{w_2})(t_2 - t_3) S_{h_2}$ (32)
$= 278{,}062$ calories.

$W_{s_4} = (W - W_{w_1} - W_{w_2} - W_{w_3})(t_3 - t_4) S_{h_3}$ (33)
$= 281{,}183$ calories.

If these values are now deducted from the total heat consumptions of the different bodies we get the corrected quantities of heat units passing through the heating surfaces.

First body ... $Q_1 = 7{,}029{,}132$ calories.
Second body . $Q_2 = 6{,}023{,}570.5 - 368{,}752 = 5{,}654{,}818.5$ calories.
Third body .. $Q_3 = 6{,}293{,}031.36 - 278{,}962 = 6{,}014{,}069.36$ calories.
Fourth body . $Q_4 = 6{,}558{,}052.19 - 281{,}183 = 6{,}276{,}869.19$ calories.

Calculation of Heating Surfaces.

The heating surface of an evaporating apparatus can be calculated, as we saw before, from the equation (9)

$$H = \frac{Q}{C(T - t)} \text{ where}$$

Q = quantity of heat passing through the heating surface in calories.
C = heat transmission coefficient per square meter and hour.
T = temperature of heating steam.
t = temperature of boiling liquor.

With regard to the heat transmission coefficient for a quadruple effect, it is different in each body on account of the difference in pressure. Further, because of its low pressure, the heating steam never flows constantly with the same velocity and sometimes even passes too slowly and has to be helped along by means of air-vents to make it move a little more rapidly. The cleaning condition of the heating steam pipes has also a great influence.

Dr. H. Claassen made experiments on sugar evaporation, and by using his and other observations Hausbrand has calculated the following ratios for a quadruple effect:

1 : 0.91 : 0.75 : 0.55

In our case the heat transmission coefficients, therefore, become:

First body ..... $C_1 = 2184$
Second body ..... $C_2 = 1987$
Third body ..... $C_3 = 1638$
Fourth body ..... $C_4 = 1200$

Assuming that the heating steam enters the heating surface of the first body at 1.5 atmospheres absolute pressure corresponding to a temperature of 112° C., then:

$$H_1 = \frac{7{,}029{,}132}{2184 \times (112 - 100)}$$
$= 268$ square meters.

$$H_2 = \frac{5{,}654{,}818}{1987 \times (100 - 90.27)}$$
$= 294$ square meters.

$$H_3 = \frac{6{,}014{,}069}{1638 (90.27 - 79.65)}$$
$= 346$ square meters.

$$H_4 = \frac{6{,}276{,}869}{1200 \times (79.65 - 60)}$$
$= 266$ square meters.

On account of the above mentioned uncertain conditions of the heating surfaces, it is advisable to increase somewhat the sizes calculated from the formula. We make the following corrections:

$H_1 = 280$ square meters.
$H_2 = 310$ square meters.
$H_3 = 365$ square meters.
$H_4 = 280$ square meters.

Calculation of Connecting Pipes.

The most important parts of a quadruple effect are the vapor-connecting pipes between the different bodies. These can be easily calculated, as we have determined the evaporated quantities of water. For this purpose the following formula can be used:

$Q = K A v$ (34)

Where

Q = the volume of steam in liters passing through the connecting pipes.

$$Q = \frac{W_w}{3600} \times \frac{V}{1000}$$

Where

W_w = weight of evaporated water in the bodies in kgr. per hour.
V = the volume of one kgr. vapor in liters.
K = coefficient, with an approximate value of 0.8.
A = cross-section of steam pipe

$$\frac{d^2 \pi}{4}$$

d being the diameter of the pipe.
v = velocity of vapor in meters per second.

$$\frac{W_w}{3600} \cdot \frac{V}{1000} = \frac{d^2 \pi K v}{4} \quad (35)$$

According to the experiments made by Regnault the approximate volume of one kgr. of vapor occupied in the different bodies at the existing pressures is:

First body ..... 1699 liters.
Second body ..... 2268 liters.
Third body ..... 3446 liters.
Fourth body ..... 7747 liters.

The velocity v of steam may be taken 30 meters per second for the first three connections and for the fourth discharge of vapors into the condenser as 50 meters per second.

From the above equation we get

$$d = 0.121 \sqrt{W_w V} \quad (36)$$

for the first, second and third bodies, and

$$d = 0.094 \sqrt{W_w V} \quad (37)$$

for the fourth body to the condenser; consequently

$d_1 = 0.121 \sqrt{W_{w_1} V_1} = 528$ mm.
$d_2 = 0.121 \sqrt{W_{w_2} V_2} = 610$ mm.
$d_3 = 0.121 \sqrt{W_{w_3} V_3} = 774$ mm.
$d_4 = 0.094 \sqrt{W_{w_4} V_4} = 926$ mm.

The practical diameters may be taken as follows.

$d_1 = 550$ mm.
$d_2 = 640$ mm.
$d_3 = 800$ mm.
$d_4 = 950$ mm.

Calculation of Furnace Charges.

By Regis Chauvenet.

Chemical Introduction.

The computation of slags, *given*: (1) the ore and fluxes by analysis, and (2) the composition of the slag sought, has, I believe, never been made the subject of a special treatise. Several works on the metallurgy of certain metals have devoted more or less space to the topic. As a rule, the methods have lacked generality, often they were hardly "methods" properly speaking, but rather illustrations of special cases, sometimes of the "cut and try" order. A singular mystery has been thrown about the subject, which in reality presents no especial difficulties.

The slag "sought" can be attempted, of course, only when composition of ore and fluxes is known. In the iron blast

furnace we have the simplest case, because of the absence of matte-forming material, and of any reducible metals other than iron. Hence it is far more practicable in that special case to produce, by a properly calculated charge, almost the exact slag desired.

Per contra, owing to the high temperature of the iron furnace, it is less imperative to produce a slag of low-fusion temperature, so that a greater latitude of composition is allowable than in the smelting of other metals. Analyses have been published showing astonishing variations in the silica percentages of iron slags, varying from the high "twenties" up to as much as 60 per cent in extreme instances. Those who can remember the old charcoal practice of the Southern states, now nearly obsolete, may also call to mind the "slag wheel" by means of which the almost incredibly siliceous slag was dragged from the furnace in ropy and reluctant masses.

Some knowledge of chemistry is necessary in slag computation, and some familiarity with elementary mathematics. Efforts have indeed been made to dispense with both. The writer does not discuss either the advisability or the results of such attempts. The chemistry is limited to first principles, chiefly to the fundamental laws and their arithmetical interpretation. The mathematics are confined to the "Rule of three," i. e., ratio and proportion, and to the algebraic knowledge required to solve simultaneous equations of the first degree.

It is not without hesitation that the elements of chemical calculation are here introduced, as there are many to whom these will appear to be of too elementary a nature. However, there are many persons who have a fair knowledge of the elements of chemistry who are at a loss how to apply their knowledge when it comes to calculations of even a very simple kind. For such, a chemical epitome is prefixed, with apologies to such as do not need it.

It is convenient in the classification of slags (i. e., formulistically) to return to the old "dualistic" form. This has now become so far obsolete as to be almost unknown to the younger generation of students, and familiar only as a part of chemical history to older men.

The "dualistic" system originated with Berzelius. The transition period was from about 1850 to 1875. A few examples of the old and new formulas will serve to show the essential differences. To simplify the illustration we omit the changes in the atomic weights of the dyed elements. (Calcium 20, iron 28, etc.)

Compounds.	Old style.	New style.
Sulphuric acid	H_2O, SO_3	H_2SO_4
Tri-calcic phosphate	$3CaO$, P_2O_5	$Ca_3(PO_4)_2$
Boric acid	B_2O_3, $3H_2O$	(2) $B(OH)_3$
Ammonium nitrate	$(NH_4)_2O$, N_2O_5	(2) NH_4NO_3
Iron singulo silicate	$2FeO$, SiO_2	Fe_2SiO_4

The old system is certainly more cumbersome, and the theories upon which it rested belong to an early period of chemical development. But in a certain sense it may be well to point out that the old system is still in use, viz.: in the statement of many chemical analyses. Thus, if we have to state a phosphate analysis, with a view of presenting its percentage of available phosphoric acid, supposing tri-calcic phosphate to be one of the constituents, we would be forced to separate the "basic" and "acid" components, or the "oxide" and "anhydride" stating them as percentages, i. e., as CaO and P_2O_5, in spite of the fact that we no longer so write them in our accepted formulas.

Coming to the "silicates," which form about the only constituents of a slag, the old way of regarding the relation as one between the oxygen of the silica and the oxygen of the base still holds and is both convenient and practical. As based upon the consideration defined above, this nomenclature has the merit of great simplicity. Compare the oxygen in the silica with the oxygen in the base in the following illustrations, and no further explanations will be needed. We take the iron silicates as examples.

Formulas.	Names.
$(FeO)_2$, SiO_2	Singulo silicate.
FeO, SiO_2	Bi-silicate.
$(FeO)_2$ $(SiO_2)_3$	Tri-silicate.
$(FeO)_4$ $(SiO_2)_3$	Sesqui-silicate.

A glance at these formulas shows that when the oxygen of the silica equals that of the base we have the "singulo," when twice that of the base, the "bi-silicate" and so on, the three-to-two relation taking the usual designation of "sesqui."

Written in modern form these silicates would read as follows:

Fe_2SiO_4	"Singulo"
$FeSiO_3$	"Bi-"
$Fe_2Si_3O_8$	"Tri-"
$Fe_4Si_3O_{10}$	"Sesqui-"

Evidently if we are to see the "oxygen ratio" in complex formulas of the modern type, we must first "dissect" them.

So much for the ordinary slag nomenclature, in which we leave out for the present any discussion of the almost universal fact that in practice all slags are "polybasic."

To assume that the reader of this article is unacquainted with the elements of theoretical chemistry would be going too far. It is hardly possible to introduce the topic of calculations based on formulas and equations without making certain assumptions as to the fundamental knowledge of the reader, and as it is necessary to be definite in this respect, we here indicate what is supposed to be known, putting it into the form of condensed statements of laws and definitions, to refresh the memories of such as may not have had recent occasion to use them.

The definitions are conventional and wholly disregard all theories as to the nature of "atoms" and "molecules." In short, "stoichiometry," the "arithmetic of chemistry," is independent of the theory of the subject, but it is convenient, in fact almost inevitable, that it should make use of its language.

"Atomic weights" then, for our purpose, are the ratios in which, or in simple multiples of which, the elements unite among themselves.

The "molecular weight" of a substance is the sum of the atomic weights contained in its molecule.

The symbol of an element carries with it "understood" its atomic weight.

A chemical equation represents some chemical action. Its members must be equal in "weight" and in atoms of each element respectively ("balance"), thus illustrating the law that the mass of matter is not changed by a chemical reaction.

"Actual and atomic weights are proportional."

This simple dictum involves nearly all of the "mathematics" used in computing from chemical formulas. It need hardly be pointed out that the statement applies to "molecular weights" as well.

As it is unnecessary in slag work, to regard fractional values of the atomic weights, we shall use the following table in which only the nearest units are indicated.

Elements.	Atomic weights.	Elements.	Atomic weights.
Al. Aluminium	27	Pb. Lead	207
As. Arsenic	75	Mg. Magnesium	24
Ca. Calcium	40	Mn. Manganese	55
C. Carbon	12	O. Oxygen	16
Cu. Copper	64	Si. Silicon	28
H. Hydrogen	1	S. Sulphur	32
Fe. Iron	56	Zn. Zinc	65

The above are all of the elements we shall use in the examples to follow. The student should never attempt to "memorize" a table of this kind; this leads to confusion and error. By *using* it as a reference one soon associates the symbol and atomic weight properly.

It remains only to say that the subscript letters in formulas multiply the atomic weights of the elements to which they

are annexed. Thus Fe goes into our calculation as 112, SiO as 60; $CaCO_3$ as 100; 2CaO is the same as $(CaO)_2$; the comma will be used only to subdivide "dualistic" compounds, as for instance FeO, SiO_2 bisilicate of iron.

Chemical Introduction.

Chemical Arithmetic ("Stoichiometry") may be treated almost wholly by the use of the rules for "Ratio and Proportion." Knowledge of this and (later in the series) of simple equations, is assumed on the part of the reader.

Problem I. Given the weight of any substance forming one term of a chemical equation, to deduce the weight of any other term.

Examples. (a) $SiO_2 + 2FeO = (FeO)_2, SiO_2$

If the SiO_2 (silica) weighs 50 lb., what will be the weight of the iron oxide which combines with it in this ratio (singulo silicate)?

Solution. Molecular weight of SiO_2 = 28 + 32 = 60.

Molecular weight of $2FeO = (56 + 16) \times 2 = 144$.

Since atomic (or molecular) weights represent actual numerical relations these molecular weights are in the same ratio as the *actual* weights in any given case, hence:

$$SiO_2 : 2FeO = SiO_2 : 2FeO.$$
$$60 : 144 = 50 = 120$$

It will then take 120 lb. of ferrous oxide to combine with silica in the singulo silicate ratio.

A very good, although quite conventional rule in working these proportions, is always to place the "theoretical" weights on the left and the actual weights on the right, bringing the unknown term last in the series, as in the above example. We use the equality sign rather than the "four dots" in our proportions. In fact, a proportion is nothing more than an expression of the equality between two ratios, and it might as well be so written.

Translated into ordinary language we say: "Molecular weight of silica is to molecular weight of two molecules of ferrous oxide, as actual weight of silica is to required weight of ferrous oxide."

(b) $Fe - H_2SO_4 \quad FeSO_4 - H_2$.

If we have 7 lb. of sulphuric acid, what weight of iron will it dissolve?

Atomic weight of iron = 56.

Molecular weight of sulphuric acid = 2 + 32 + 64 = 98.

It frequently happens that the ratios can be simplified. In the first example we might have written in the first member 5 : 12 instead of 60 : 144. In this case we write:

H_2SO_4 : Fe — H_2SO_4 : Fe
98 : 56 — 7 : 4 = 7 : 4

Answer—Four pounds of iron.

(c) One hundred pounds of lead sulphide is roasted to lead sulphate. What is the gain in weight?

PbS $PbSO_4$ 239 : 303
239 : 303 : 100 : 126.7

Answer—Weight of the sulphate 126.7 lb. Gain in weight 26.7 lb.

The following examples are given with answer, but no solution, as an exercise for the reader.

(d) An ore contains by analysis:

FeS_2	48.00 per cent
ZnS	24.25 per cent
SiO	27.75 per cent
	100.00 per cent

It is roasted, with reactions, as below:

$$4FeS_2 + 11\ O_2 = 2Fe_2O_3 + 8SO_2.$$
$$ZnS + 2\ O_2 = ZnSO_4.$$

Assume that 100 lb. was originally taken. What is the change in weight, after roasting?

Answer—No change in weight.

(e) $CaCO_3 = CaO + CO_2$.

This equation represents the burning of limestone to produce quicklime. We want 100 lb. quicklime (CaO). What weight of the limestone must we take?

CaO $CaCO_3$ 56 100
56 100 100 178

Answer—178+ lb.

(f) Three tons of pyrite (FeS_2) are roasted to Fe_2O_3 (ferric oxide). What will be the weight of the latter?

Note that there is but one "Fe" in the formula of FeS_2 and two in the formula Fe_2O_3. We shall also find that we cannot equate this "roast" without taking eleven molecules of oxygen, thus:

$4FeS_2 + 11O_2 = 2Fe_2O_3 + 8SO_2$.

Answer—Two tons.

Quite a variety of problems of metallurgical application can be brought under the operation of this general rule. It is only necessary to know the chemistry of the reaction, that is, by its equation. Sometimes it is not even necessary to understand the equation of reaction, see problem (c) above, in which we wrote simply the formulas for the original substance and that of the roasted product.

Problem II.—To find the percentage of any constituent in a chemical compound, the formula being given.

Example. (a) Find percentage of silica in the silicate (singulo) of iron $(FeO)_2, SiO_2$.

Solution.—First write out the theoretical composition in molecular weights, *e. g.*:

$(FeO)_2 = 144$
$SiO_2 = 60$

Molecular weight of compound = 204.

It is evident that the total "weight" is to the weight of silica as 100 is to the percentage of silica, that is:

$$204 : 60 = 100 : 29.4$$

Answer.—29.4 per cent silica.

This operation is too frequently performed and of too simple a nature to require the setting down of the proportion. *Divide molecular weight of the substance whose percentage is sought by the molecular weight of the whole compound*, then shift decimal point two places to the right, *i. e.*, multiply by 100.

By extending this to all of the constituents we get the "translation" of a formula into an analysis expressed in percentages.

(b) What is the percentage analysis of ferric oxide, Fe_2O_3?

Solution. $Fe_2 = 56 \times 2 = 112$
$O_3 = 16 \times 3 = 48$

Molecular weight of ferric oxide = 160
Per cent of iron calculated as in (a) = 70.00
Per cent of oxygen calculated by same = 30.00
Summation 100.00

A few cases are appended, answers given, but no operations. The "problem" in fact hardly deserves the name.

(c) Find analysis of Dolomite; $CaCO_3 + MgCO_3$.

Divide the percentages as follows, viz., into CaO, MgO and CO_2.

Answer.

CaO	30.4 per cent
MgO	21.7 per cent
CO_2	47.8 per cent
Total	99.9 per cent

(d) Find analysis of the mineral Cryolite; Na_3AlF_6.

(Atomic weights Na = 23. F = 19.)

Answer. Na_3 = 32.8 per cent. Al = 12.8 per cent. F_6 = 54.3 per cent. Total 99.9 per cent.

(e) Find analysis of the silicate FeO, SiO_2.

Answer.—FeO = 54.5 per cent. SiO_2 = 45.5 per cent. Total 100 per cent.

Problem III.—To translate an analysis into a chemical formula. This may or may not be possible. If, however, the

substance analyzed is a true chemical compound, the transformation is not difficult

Example.—(a) Take example (b) under the last problem and reverse it, that is, let composition by analysis be: Iron 70 per cent, oxygen 30 per cent. Divide each percentage by the atomic weight of the element represented, the quotients will obviously stand in the *relative* relations of the numbers of atoms present. Thus:

$$\frac{70}{50} = 1.250 \text{ and } \frac{30}{16} = 1.875.$$

If we take care to keep the decimal places the same in the two quotients we may drop the "points" as the ratio remains the same, so we write 1250 and 1875.

These numbers are evidently in the ratio of 2 to 3. We may write the formula: Fe_2O_3.

It is not always so easy to see the ratios, but by applying the rule of "greatest common diviser" any numbers which are in simple ratio can readily be reduced to their lowest terms.

Usually a slag analysis will not yield an exact formula, but it is often possible to find a close approximation.

Example.—(b) Analysis; $SiO_2 = 47$ per cent. $FeO = 38$ per cent. $CaO = 15$ per cent.

Apply the rule as above, we find as quotients:

$$(SiO_2)\ \frac{47}{60} = .783. \quad (FeO)\ \frac{38}{72} = .528. \quad (CaO)\ \frac{15}{56} = .268.$$

In cases like this, when we find that we can get no "greatest common divisor," a little judgment comes in. A person endowed with some "arithmetical perception" (a faculty hardly to be taught) will not be long in finding an adjustment which will lead to an approximate result. In the present instance, if we merely drop the third figures we find that we have to compare the numbers 78, 52 and 26, greatest common divisor = 26, so the three are in the simple ratio of 3:2:1. That is, we have three molecules of silica, two of iron oxide and one of lime, very nearly, and may write the formula:

$$2(FeO,SiO_2) + CaO,SiO_2.$$

The accurate analysis of the slag above was purposely thrown a little out of adjustment, to indicate how such approximations should be treated. No fixed rule can be given for such adjustments, if the numbers fail to yield an exact simple ratio. This case is really closer to a "formula" than should be expected in practice.

(c) Find formula for a compound analyzing:

$Al_2O_3 = 25.6$ per cent. $CaO = 14.1$ per cent. $SiO_2 = 60.3$ per cent.

Answer.—$Al_2O_3,(SiO_2)_3 + CaO,SiO_2$.

This problem admits of many interesting illustrations and extensions, but as its application in practical metallurgy is limited we content ourselves with these examples. The next one, however, is of constant use in a certain kind of slag computation and should be thoroughly understood before proceeding.

Its principle is the same as used in problem I.

Problem IV.—To calculate a chemical "excess" or "deficiency."

Example.—(a) The slagging constituents of a roasted ore are confined to silica and iron; analysis shows:

$SiO_2 = 40$ per cent, $Fe_2O_3 = 30$ per cent.

What is the silica excess in percentage over the formula $(FeO)_2SiO_2$?

Solution.—Molecular weight of $SiO_2 = 60$. Mol. wt. of $2FeO = 144$. Since the analysis shows ferric oxide, this must be reduced to ferrous oxide, their ratio being 160 to 144 or 10:9. This gives 27 per cent ferrous oxide.

We have then: $2FeO:SiO_2 = 2FeO:SiO_2$.

$$144:60\ (=12:5) = 27:11.25.$$

This shows the silica "required" for the ferrous oxide on the formula given. Actual silica is 40 per cent; subtracting the 11.25 we get 28.75 per cent.

Answer.—Silica excess = 28.75 per cent.

That is, in computing for a flux to be added we must provide for 28.75 lb. silica in each 100 lb. of the ore charged.

The next example is a "mixed" case, viz.: partly formulistic and partly arithmetical.

(b) An ore has as slagging constituents:

SiO_2, 30 per cent. FeO, 20 per cent. All other bases, 20 per cent.

We decide to flux on the convention that the FeO shall be to silica in the chemical ratio of $2FeO:SiO_2$, and that the weight of all the other bases shall be twice that of the silica provided for them. The latter part of the condition is what we term the "arithmetical" one. Find SiO_2 excess.

We start as before:

$$2FeO:SiO_2 = 2FeO:SiO_2$$

$$144:60\ (=12:5) = 20:8.33.$$

That is, the iron will take 8.33 per cent of the silica. Subtracting this from the 30 per cent of the analysis leaves 21.67 per cent silica, *available* for bases other than the iron. But as we require that all other bases shall be twice the weight of the silica provided for them, and as we have 20 per cent of these "other bases" in the ore, we subtract 10 per cent (half of twenty) more from the silica, so we have still left 11.67 *as "silica excess,"* and the amount of bases to be now provided for fluxing this ore will be 11.67×2 or 23.34 per cent. That is, using 100 lb. as unit weight of ore, 23.34 lb. base to be provided. *Answer.*—Silica excess = 11.67 per cent.

(c) Keep the statistics and results of example (b); let us further suppose that we have a limestone which contains:

Silica, 5 per cent. Lime (CaO), 53 per cent.

How much of this material will it take to satisfy the requirement of 100 lb. of the ore of example (b)?

Solution.—The 5 per cent silica of the limestone will call for twice its weight of lime, viz.: 10 per cent, leaving 43 per cent *available* lime for the silica of the ore. From last example we know that we need 23.34 lb. net base for each 100 lb. of ore, so the question is now reduced to this; "How many pounds of limestone with 43 per cent excess CaO, will furnish 23.34 lb. of the required (excess) base?"

$$43:100 = 23.34:54.$$

Answer.—54 lb. of limestone.

In any case similar to "c" a rule might be made, viz.: "Divide requirement by excess and multiply the result by 100."

(d) Ten pounds sulphuric acid dissolve 3 lb. of iron, how many pounds of zinc will the excess acid still dissolve?

Answer.—3.15 lb.

(e) An ore contains as "slag constituents" the following:

Silica	14.00 per cent
FeO	18.72 per cent
CaO	7.28 per cent

It is proposed to produce a singulo silicate slag. Adjudicated with this formula in view, what is in excess in the ore itself, by what weight, and of what substance. Assume 100 lb. of ore taken.

Answer.—Silica excess, 2.3 lb.

These elementary examples must serve as our chemical introduction. Their principles may be carried into far more complex problems.

If cases arise which the reader cannot state let him revert to the general rule, which is based on the fundamental facts of chemistry, viz.: "Atomic (or molecular) weights and actual weights are in the same ratios."

The method of application may not always be obvious, but in a great majority of cases this will be found to give the clue for a correct statement of conditions.

The calculations of furnace charges will be taken up in detail in several further articles.

Denver, Col.

Flow of Heat Through Contact Surfaces

By Carl Hering.

In the previous issue of this journal the writer published a table of values of the thermal resistivities of a number of materials, based on data gathered from various sources and there reduced to a common unit, the thermal ohm, that is, the degrees per watt.*

The purpose of the present article is to supplement this with a similar table, giving the values of the flow of heat through surfaces of contact between bodies and their equivalent thermal resistances, also collected from various sources and here reduced to watts and thermal ohms. Such figures are sometimes of importance in electric furnace work and in general in many other cases involving the flow of heat, when such a flow passes from one body to another through their surface of contact.

Such cases arise, for instance, in determining the heat lost to the air from the outside of a furnace wall, or from the top of a charge or a hot crucible, also the heat carried off by water cooling or in general when heating liquids, solids and gases in contact with one another.

A number of phenomena show that the thermal resistance of a contact between two surfaces may be very high, so high in fact that the resistances of the bodies themselves may sometimes be insignificantly small in comparison; it therefore at times becomes very important to take it into account in thermal problems. For instance, the contact resistance of the flames and the outside of the water tubes of an ordinary steam boiler, is extremely high; the heat gradient falls from the temperature of the hot flames to nearly that of the steam in a distance of apparently only a few thousandths of an inch, hence is an enormously steep heat gradient; a postage stamp pasted on the bottom of a tin cup in which water is boiled with a large Bunsen flame, will not even char, yet if increased to several thicknesses of stamps the outside ones will char, showing the extreme thinness of this high resistance layer. With such a high contact resistance no difference could be noticed between copper and iron pipes in boilers, although the latter have four times the thermal resistance of the former.

It is also known that a jointed graphite electrode may become red hot up to the joint and yet be black on the other side of it. It is said that invisible cracks in iron can be noticed by heating the piece so that the heat flows through it; it will flow readily up to a crack but only very slowly across it.

A recently described experiment (see this journal, November, 1911, p. 568) illustrated how very much greater the thermal resistance was from red-hot copper to the air, than through an equal section of copper.

This contact resistance from a hot body to the air may at times be sufficient to affect the temperature which the outside of a furnace will assume, hence, also, the amount of the loss through the walls. When the chief insulation resistance is in the walls this contact resistance on the outside will probably not be important, but when the flow of heat from the outside surface is great the contact resistance might become appreciable. Being a cheap form of resistance which occupies no space and weighs nothing, it might possibly even be made use of for insulation. One form in which it seems to be readily available is in the joints between the bricks or layers of the walls, instead of filling these solid with mortar, air spaces may be left to advantage and the bricks may preferably be laid with their flat sides perpendicular to the direction of flow so as to make as many joints as possible across the path. In one of the writer's furnaces constructed in this way the outside remained surprisingly cool even for high steel-melting temperatures inside.

Another instance of contact resistance and one which is of special importance in some electric furnaces is shown quite strikingly in the melting of scrap metals. When the pieces are forced into a bath of molten metal so as to become wetted by the liquid whereby the contact resistance is destroyed they take up the heat with far greater rapidity than when heated in the gases above the charge or by radiation from above; the difference is quite striking. Hence in a resistance furnace in which the heat is generated in the liquid metal it can be transmitted to the cold metal with very great rapidity and with practically perfect economy by thus eliminating the contact resistance, thereby reducing considerably the stand-by losses per ton and increasing the daily tonnage of the furnace.

Unfortunately our knowledge of such contact resistances and the laws governing them are very meager, hence our only recourse at present seems to be to take what experimental data exists and apply it as best we can. The table of data given below was compiled for this purpose and may be of value until better and more reliable experimental or analytical data become available. All the data have here being reduced to watts and thermal ohms, as these are the most rational units, being decimal multiples of the true absolute units. They are also the most convenient ones for the electric engineer for expressing a flow or transmission of energy in the form of heat; it is then in terms of the same unit in which the energy is expressed and measured in its electrical form, hence all the troublesome conversion factors are eliminated from the calculations. It is entirely unnecessary, besides being somewhat absurd, to change over from one unit to another and an incommensurate one at that, as the energy changes from the electric to the thermal form; it is the same energy, then why change units.

There are no less than 18 (perhaps even more) possible units in which a flow of heat can be expressed, beside 72 for thermal conductivity and an equal number for thermal resistivity, making a grand total of 162 possible units to choose from, and some writers seem to feel charitable toward those which they think have been slighted by others. Hence, by thus reducing all data to one standard uniform unit of heat flow, the watt, it becomes possible to compare the results of different observers directly, whereby a better choice of the more probably correct ones may be made.

Unfortunately it is quite common to use the word "radiation" very loosely and at times in a positively incorrect sense. In its correct sense it is used to distinguish the heat which is transmitted by true radiation from that transmitted by conduction and convection; notwithstanding this it is very often used for the total heat including that conducted and that conveyed. For instance, the losses through furnace walls governed probably almost entirely by conduction, are generally referred to as "radiation losses." A steam radiator is so called, although most of its heat is given off by convection. Some of the discrepancies in the data given in this table may, therefore, be due to some writers making the distinction and others being loose in their terms.

The term contact resistance has been used above as a convenient self-explanatory expression; whether the evidently great opposition which a flow of heat encounters at such surfaces, is a true resistance measurable in thermal ohms, may be open to question; the term virtual resistance would probably be a better one. It may, perhaps, be a different physical property, just as a counter e.m.f. in electric circuits is not a true resistance, although its value may, at times (but with caution), be expressed in its equivalent in ohms.

If this so-called thermal contact resistance were a true resistance, then the flow should increase in proportion with the temperature drop at the surface; that is, temperature drop/watts $= R$ should be constant. This is not the case, however, as the flow of heat from a surface to the air per degree of difference increases quite rapidly with the temperature; this is due in part to the fact that the radiation heat increases very rapidly with the temperature (with the fourth power of the absolute temperature and even faster), and whether it would be correct to speak of a resistance to radiant heat or not, is questionable, although its counterpart seems to be implied in radiant light in the terms translucent, trans-

*This journal, Dec., 1911, p. 675.

parent and opaque, and we know that a screen will intercept radiant heat by offering a resistance and it does not do this by radiating back an equal amount, but by an actual stoppage.

It is quite as correct, however, to express these surface resistances in thermal ohms as it is to reduce the heat flow to that per degree, which is done in many text books and tables. Hence the resistances have been added here for a square inch. They are merely the reciprocals of the watts per square inch, per degree, or the quotients of the temperature drop divided by the watts per square inch. They decrease very greatly when the temperatures become very high; for the theoretical "black body" this contact resistance may be zero in thermal ohms.

But, whether a surface resistance is a true resistance or not for practical purposes it is of service in simplifying calculations to express the resistivity (specific resistance) of a contact resistance in terms of a true thermal resistance like thermal ohms, and in order to correct it for higher temperatures it may be accompanied by a temperature coefficient, just as is done with the resistivities of solids. It would then have a negative coefficient, that is, it would decrease as the temperature rises, just as most refractory materials do; this decrease is shown very markedly in the table. But this is foreign to the present article.

To use such a figure for contact resistance one simply adds it to that of the body itself in order to get the total; then by dividing the total temperature drop (therefore including that at the surface) by this total resistance gives the total loss. In other words, it is treated simply as an ordinary resistance whose length (the thickness of the high resistance surface film) may be neglected. To find this contact resistance for a given surface, like the outside surface of a furnace, divide the thermal ohms per square inch as given in the table, by the total surface in square inches.

For a warm surface of ordinary iron, for instance, the surface resistance may be about 100 thermal ohms per square inch, hence for every square foot it would be $100/144 = 0.7$ thermal ohms, which is then added to that of the wall to get the total of that column of one sq. ft. section. The temperature drop will then, of course, be dependent on the flow of heat, and this should be of the order of about 0.4 watt per sq. in., hence about 58 per sq. ft. for which 100 thermal ohms was the contact resistance. It is, therefore, a calculation by trials, instead of a direct one, but this is true also of the flows through solid materials which also have a large temperature coefficient.

One of the complications which arises in reducing such thermal data as these to laws, is that when heat flows from a solid to air, as in exposed hot bodies, the flow *per degree* increases as the temperature rises, while when it flows in the reverse direction, from a gas to a solid, as in the case of the hot gases in a boiler heating the water tubes, just the reverse seems to be true. It has even been suggested to increase this heat flow per square foot through the tube walls by using lower temperature gases or liquids for heating the tubes.

Another complication in establishing such laws is shown in the spheroidal state. Ordinarily when heating water in an iron vessel, by means of very hot gases, as in a steam boiler, the high thermal resistance is on the fire side of the iron, but if given the opportunity it will quickly shift over to the water side, producing what is known as the spheroidal state, and it seems that it also increases as it changes its place.

Still another complication is due to the fact that when heat flows from a solid to a liquid, convection plays an important part, hence also the velocity of movement of the liquid. And with a gas there is radiation besides, which at times may become relatively large; in both there may or may not also be true conduction of the liquid or gas. Radiation per degree is known to increase rapidly as the temperature rises, but the laws concerning convection are not so definite, and in practical work we are generally concerned with the total and do not care for each one separately. Radiation laws apply strictly to a very useful theoretical creation called a "black body," namely one which absorbs all radiations falling on it and does not reflect or transmit any. For such bodies the radiated energy is proportional to the difference between the fourth powers of the absolute temperatures of the emitting and the receiving body. But for most actual bodies this must be multiplied by a very appreciable factor which is quite different for different materials and even varies very considerably with the temperature, all of which makes it necessary to go back to empirical data.

At best, therefore, any theoretical calculations of heat flows through contact surfaces would be likely to be quite complicated, and even then they might give very erroneous results owing to the apparently great differences between the physical conditions of the contact surfaces. For these and other reasons it will probably in most practical cases be best to use actual observed data, hence this table was prepared. It is also hoped that the inconsistencies in these results, which become more apparent by their direct comparison, as also the vagueness of some of the original data, will induce those who have the time and facilities to do so, to make more systematic and more complete re-determinations.

Owing to the shifting nature of this high resistance layer, generally to the gas side, the results are here arranged in various groups, as it may not always be proper to expect those in one group to agree with those in another. A number of data have been included for comparisons rather than for their direct use.

These tabulated results seem to enable the following general conclusions to be drawn; in doing this, however, the writer assumes no responsibilities for the correctness or reliability of the original data, but merely for their reduction to a uniform basis. References to all the original sources are given in the notes following the table.

Solid to solid. This applies to such cases as joints between bricks or layers, or between two parts of a jointed electrode, or between an electrode and its terminal, etc., in general, to any butted surfaces of solids which are not united by mortar, fluxing material, solder, etc., which destroy the contact resistance by making the parts mechanically continuous. No data could be found. It is known that for the good conductors like the metals, or graphite, the resistance of a crack is relatively very high. For insulators it seems also to be considerable, but as the material itself also has a high resistance the relative difference may be less. In water-cooling hot parts it seems important to avoid such abutting surfaces as much as possible between the wetted surface and the part to be cooled. Snyder* believes that the high resistance of joints between solids decreases very greatly at the higher temperatures.

Solid to gas. These results apply to such cases as the outside of furnaces, the cooling of the top surfaces of molten or hot charges, or of the outside of crucibles, etc. Only one contact surface is involved. They seem to show that with about ½ watt per sq. in., the surface is quite warm to the touch; with about 1 watt it would no doubt sizzle if wetted. With 3 or 4 watts, or roughly, half a kilowatt per sq. ft., it would be decidedly too hot to touch. At a dull red heat a metal surface exposed freely to the air would probably be losing about 7 to 11 kilowatts per sq. ft. At a bright red heat the loss from a metal surface or a hot crucible might be of the order of 12 to 15 kw per square foot; but with a still atmosphere of hydrogen, as in the molybdenum wire furnace, such very high temperatures as 1600° to 1700° C. are reached with only about 4½ to 8 kw per square foot, which is probably due more to the relative stillness of the heated gas than to its being hydrogen.

The results for the very thin wires from which the emission is enormous, due in part to their small diameters, are not

directly comparable as the surface action of a very thin round wire seems to be different from that of a flat surface. It is of interest, however, that as high as 9000 kw per square foot are thus emitted to a gas, as distinguished from the usual vacuum. A vacuum reduces very greatly the flow from a surface, as is shown for instance by the rather low heat emission from the graphite surfaces in the Arsem furnace.

If the flow of heat through furnace walls amounts to 1 kw per square foot of inside surface (see this journal, November, 1911, p. 591), and if the flare to the outside is 3.5, then the flow of heat from the outside to the air would be $1/3.5 = 0.286$ kw per square foot. From the table it appears that this would be only about five times that escaping from dynamos when the rise of temperature is about 40°, less than half that for 200°, and only about double that from an ordinary steam radiator (see below); hence the outside of such a furnace would not be likely to get very hot, probably not much more than about 150° C. As this is a small drop of temperature compared with the total, this skin resistance is a small part of the whole, in this particular case.

When reduced to the heat emitted per degree, the results show that the earlier values of Peclet and of Box are either much too low or apply only to atmospheric temperatures; they may apply to true radiation only. They are of interest, however, in their relative values; they show how very greatly polishing a surface reduces its power to transmit heat to the air; it reduces it to about 1/6 to 1/7. This is also shown by the relative values for iron given at the end of this group; these also seem to show that oiling a polished surface increases the emission between two and three times, but has less effect on rough surfaces.

A fairly good, easily remembered approximate figure for ordinary iron surfaces for steam temperatures seems to be about 1/100 watt per C° per square inch. With from 3 to 15 watts per square foot per C°, the temperatures range from high steam heat to bright red heat for exposed surfaces, while with only 3 to 5 the temperature will be a white heat with a still gas, showing the very great effect of the movement of the gas. In a vacuum, about 4 watts per square foot per C° corresponds to 2000°.

Metal to Water.—These apply chiefly to water cooling, as for instance of electrode terminals. The data is very meager. It seems, however, that roughly as much as 100 kw per square foot of wetted surface can be relied upon without steaming, in brass cooling jackets, with but a moderate flow of water. Roughly this is about 1 kw per C° per square foot.

Water to Metal to Water.—Roughly about 1½ to 2 watts per square inch per C°.

Water to Metal to Air.—These apply more directly to hot water heating of rooms, and if it may be assumed that the high resistance is almost entirely on the air side, which is likely, then the results may be compared with the second group. About 50-90 watts per square foot seem to flow when the water is very hot. Reduced to 1°, a fairly good crude figure seems to be about 1 to 1½ watts per square foot; this increases with the temperature. Comparing these with those of the second group, they will be seen to be of about the same order of magnitude, which seems to show that the contact resistance resides almost entirely on the gas side.

Gas to Metal.—These apply to the heating of metals in flame furnaces, or to the flame side of steam boiler pipes. No data was found, but as has already been remarked there seems to be a very high contact or skin resistance, which in steam boilers is known to be remarkably high, and is very noticeable in the melting of metals, for when cold metal is submerged in liquid metal it acquires heat with far greater rapidity; theoretically most metals should sink in their melts, but in practice they unfortunately very often float on cushions of frozen high resistance slag, hence must be heated largely from the top by the gases and by radiation. It is believed by the writer that at first, when the metal is cold, this contact resistance when metals are melted with hot gases is approximately of the order of that in steam boilers discussed below, but probably somewhat less, and that it no doubt becomes much less per degree as the temperature of the solid metal rises.

Gas to Metal to Water.—These apply to steam boilers, condensers, etc. According to standard boiler practice the flow through the tubes is a little less than a kilowatt per square foot. Comparing this with the writer's rough figure for water cooling without steaming, namely 100 kw, it would seem that immensely more heat could be transmitted per square foot to the water in boilers without reaching the spheroidal state. Moreover 1 kw flowing through 1 sq. ft. of pipe, say ¼ in. thick, at about 0.8 thermal ohm, inch cube (see table in last month's issue), would mean only about 1.5° difference in temperature between the outside and inside, hence showing that the resistance is almost entirely on the outside between the gas and the metal, and that it is extremely high, indicating considerable room for improvement in steam boilers.

The single value given for this high temperature case per degree, for a locomotive boiler, roughly about 0.01 kw per square foot, seems to be in error, as it would, when compared with standard practice, mean only about 100° C. excess of temperature of the hot gases over that of the steam. But dividing the figure above it, which is standard practice, by say 1000° C. will give roughly 0.001 or only 1 watt per square foot per degree, which is only about 1/200 to 1/400 of the flow of heat through condenser tubes per degree, when the hot gas is steam. This again emphasizes the high resistance between a high temperature gas and relatively cold metal.

For condenser tubes the rate per degree is seen to be about 0.2 to 0.4 kw per square foot. The condenser tube rate is between 200 and 300 times as great as in hot water heating (see above), showing again the high resistance to air in the latter, as compared with water in the former.

Gas to Metal to Gas.—These refer chiefly to steam heating. Approximately the figures are about 100 to 200 watts per square foot, which is roughly from two to four times as great as for hot water heating; but this is due largely to the higher temperatures, for the values per degree are not very different. These latter values differ so greatly among themselves and depend so much on the movement of the air that a more careful comparison would hardly be warranted. But they seem to agree approximately with those for metal to air for similar temperatures, which would indicate that the high resistance was to the cold gas on the outside rather than from the hot gas to the metal on the inside, that is, the metal seems to tend to take the temperature of the hot gas rather than the colder one, when the latter is a gas, but the reverse when the colder body is water, as in steam boilers.

Reduction Factors.—The following reduction factors will enable those who prefer to use the older units to make the necessary reductions. 1 watt = 0.238882 small calories per second; 1 kw = 56.8776 b.t.u. per minute. 1 watt per square foot per C° = 1.90 b.t.u. per hour, per square foot, per F°. A drop in C° × 9/5 = the drop in F°.

Mr—G. S. Merrill. New Metallic Filament Lamps. *Jour.* Frank. Inst., April, 1911, p. 391.

P—Peclet. "Supplee's Mech. Eng.," 2d Ed., p. 497. Termed "radiation" but presumably means total transmission.

S—F. Schumann. "Supplee's Mechan. Eng.," 2d Ed., p. 499. A table of numerous values for different temperatures from 80° F. to 300°, for steam and water; losses by radiation and by convection, in still and in moving air. They are evidently calculated values. They are for cast iron pipes or radiators, with air temperature 70° F. The losses by convection in moving air (presumably referring to the flow in the indirect heating of buildings) are 167% of those in "quiet air," hence 2/3 greater. Those by radiation are approximately equal to those by convection in quiet air. The few figures here reduced are for the total and for "moving air."

Sn—F. T. Snyder. *Trans.* Am. Electrochem. Soc., Vol. XVIII, p. 239. Curves of values calculated from Stefan's law, Peclet's constants and Richards' formula; they include both radiation and convection. The values here chosen are those marked on the curve.

St—H. G. Stott. *Power*, 1902. A 2" bare pipe heated electrically to 188°. As the heat was generated in the pipe there was no thermal resistance in flowing into the pipe, but merely from the pipe to the air; hence probably a better figure for furnace coverings than those obtained when the pipe was heated by steam, which involves the high contact resistance of steam to pipe.

WD—Winne and Dantsizen. *Trans.* Amer. Electrochem. Soc., Vol. XX. Small furnace with wire wound around tube. The total surface of the wire was used here in deducing these figures; also the furnace temperature; that of the wire was probably somewhat higher.

X—Tests made for the writer in a university laboratory with a narrow band of nickel heated electrically, the temperature being measured with a thermo couple.

Y—Common rule for heating of dynamos, namely that the temperature rise in centigrade degrees equals 100 divided by the square inches per watt. For a rise of 40° C. this gives 2.5 sq. in. per watt.

Z—Common practice in resistances embedded in enamel on cast iron, counting one side only. One watt per square inch for every 120° F.

Dimensions of Open-Hearth Furnaces Based on Practical Data.

An interesting paper by Prof. M. A. Pawloff, of St. Petersburgh, Russia, in *Stahl und Eisen*, 1911, page 1183, gives data on dimensions of open-hearth furnaces from modern European practice.

I.—Ordinary Gas Furnaces.

The dimensions are determined by: (1) the distance between the bulkheads $= L$, (2) the distance of the long sidewalls $= E$, and (3) the height of the roof above the bottom $= h_0$. $L \times E$ may be called the bath surface S.

1. *Hearth.*—Usually based on the weight of the charge T. The ratio of bath surface S to weight of charge T is not constant in the different furnaces, but decreases regularly with increasing capacity of the furnace. This ratio depends upon the depth of the bath (in Europe not over 300 mm, or 11⅜ in., and often less) and the furnace design. Table 1 gives some ratios of modern basic open-hearth furnaces:

TABLE I.

Capacity T Tons	$\frac{S}{T}$ in Square Feet per Ton.	Bath Surface S, Square Feet.
12.5	12.9	161.5
15.	12.1	181.7
17.5	11.3	191.8
20	10.76	215.3
25	10.22	258.3
30	9.68	290.6
40	8.87	355.1
50.	8.61	430.4
60.	8.07	484.2

Sometimes we find $\frac{S}{T}$ somewhat greater, but rarely below above values. If the ratio $\frac{S}{T}$ has been well chosen, the most favorable value for T can be found only by practical experience under running conditions.

2. *Dimensions of the Furnace.*—The dimensions of the furnace are derived from the hearth. The width of the furnace in Europe is not over 11.5 ft., but in America it is as high as 14.8 ft.; the greatest length is 43 ft. The length of the furnace L may be found from the ratio $m = \frac{L}{E}$ after S has been chosen from Table 1. In general m is between 2 and 3; in Europe usually $2\frac{1}{2}$ or $2\frac{3}{4}$. For larger furnaces $m = 3$ is recommended. Therefore,

$$L = \frac{L}{m} \text{ and } S = L \cdot E = L \cdot \frac{L}{m}$$

$$L = \sqrt{S\,m} \text{ and } E = \frac{S}{L}$$

TABLE II

Relation Between Capacity, Length and Width of Open-Hearth Furnaces.

T Tons	$\frac{S}{T}$	L Feet	E Feet	S Square Feet
30	2.66	27.9	10.5	293
	2.70	28	10.3	
	2.70	31.	11.5	
40	2.75	31.3	11.3	355
	2.75	34.4	12.5	
50	2.80	36.1	11.9	430
	2.80	36.8	13.1	
60	3.00	38.1	12.7	484

3. *The slope toward the tapping hole* is greatest in the middle of the hearth, being 1/12 to 1/16 of the width, in average 0.07, which corresponds to the tangens of an angle of 4°.

4. *Furnace Volume.*—The heights h_0 above the bath for 40-50-ton furnaces should not exceed 83 in. It depends largely upon the gas quality and quantity and the process in use for making steel. Only local conditions and furnace practice will decide this question, but it can be said that oil-fired furnaces require a greater distance than gas-fired furnaces.

5. *Bulkheads.*—The air inlet area is usually 23.25-38.75 sq. in. per ton of charged material.

The gas inlet area is 1⅓-2½ times smaller than above values.

In furnaces of the same system the area of the gas inlet decreases regularly with increasing furnace capacity.

	10-Tons Square Inch.	20-Tons Square Inch.	30-Tons Square Inch.	45-Tons Square Inch.	150-Ton Mixer Square Inch.
Air inlet.	47.4	38.1	30.2	27.9	12.9
Gas inlet.	39.1	29.8	23.6	18.6	7.8
Ratio	1.214	1.281	1.283	1.5	1.66

The reason for this is that the drop in gas pressure, caused by friction, is inversely proportional to the ratio of circumference to area.

Since the ratio $\frac{S}{T}$ decreases with increasing capacity, we may also compute the area of inlets from the ratio of this inlet area to bath surface. The author found that this ratio has an almost constant value, being 3.24 sq. in. for air inlet per square foot (or 225 sq. cm per square meter).

6. Assuming the width of the inlets, the height is found from

above data. The dimensions of the gas inlets are derived from those of the air openings. The author suggests that the ratio of the cross-sections of the air inlets and gas inlets should be proportional to the quantities of heat necessary for heating air and gas or to the weights of the respective checkers.

7. *Gas and Air Flues.*—The slope of the gas flues (inlets) varies between 12° and 18°, and that of the air flues between 30° and 40°, and depends largely upon the size of the furnace. In American furnaces the gas burns almost completely, although only a single broad opening forms the gas inlet.

8. *Vertical Flues.*—Vertical flues have 25 per cent greater area than their respective inlets for the larger furnaces, and 50 per cent greater area for the smaller (20-25-ton) furnaces.

9. *Length of Bulkheads.*—The length of bulkheads depends upon the type of the different furnaces. The distance between vertical gas flues and gas inlets is between 9.8 ft. and 13.1 ft.; for air flues the distance is between 4.9 ft. and 8.2 ft.

Regenerators.

10. *Volume.*—Modern practice per ton charge is 176.6 cu. ft. checkers for small European furnaces and 123.6 cu. ft. for the largest American furnaces. In economically working furnaces, which have a low temperature drop (about 120° C. or 216° Fahr. per hour) between two reversals, the author finds that there are 90 to 110 lb. checkers per pound of coal consumed per hour.

The author recommends to base the design of the checkers on the bath surface. By using the above values of the ratio $S \div T$, the checker volume per unit of hearth surface is almost constant = 4.5 cu. m per square meter = 14.76 cu. ft. per square foot.

11. *Dimensions of Regenerators.*—The checkers in large furnaces are 80 per cent; in smaller furnaces, 70 per cent of the entire chamber volume. The depth of the checkers should not be less than 13 ft., and if possible 16 ft. The ratio between air and gas chambers varies between 2 and 1. For cool producer gas it is 1.5 and for hot gas 2; 1¾ being a fair average ratio.

Chimney Flues and Reversal Apparatus.

These dimensions are often too small, because in the case of rebuilding a furnace these parts are usually left unchanged.

12. In satisfactorily working furnaces the smallest area of air flue per 100 sq. ft. bath surface is 2 to 3 sq. ft.; the area in the reversal valves should be at least 3 sq. ft. per 100 sq. ft. hearth surface.

13. Instead of giving air and gas valve the same dimensions it is better to make the ratio of their cross-sections equal to the ratio of the cross-sections of their flues or to the ratio of their respective checker volumes.

14. *Flues Between Valves and Chambers.*—Flues between valves and chambers are made with twice the cross-section of the valve flue cross-section. Thus, for the air flue a cross-section of about 6 sq. ft. is chosen per 100 sq. ft. hearth surface.

15. *Flues Between Valves and Stack.*—The cross-sections of the flues between valves and stack should equal the sum of the cross-sections of the two flues which run to the valves of one side.

16. The same area has to be given to the stack at its base. The opening at the top of the stack is $1/20\,S$ where S is the bath surface, making the diameter $d = \frac{\sqrt{S}}{4}$

The height of stacks should be 131 to 148 ft. for larger open-hearth furnaces.

II.—Oil-Fired Furnaces.

The ratio $\frac{T}{S}$ remains the same. The distance between roof and bath has to be greater to give the oil time for complete combustion; for 20-25-ton furnaces this height should be 71-79 in. The air inlet should be 4 sq. ft. per 100 sq. ft. hearth surface.

The volume of the air checkers should be 11.5 cu. ft. per square foot hearth surface, and on account of the high heat value about 140 to 160 lb. of checker should be used per pound of coal gasified per hour.

The cross-section of the flue to stack should be about 8.5 sq. ft. per 100 sq. ft. hearth surface. The valve area and the opening of the stack at the top should be 4.25 sq. ft. per 100 sq. ft. surface.

III.—Mixers and Furnaces for Continuous Operations.

The above data cannot be applied to ordinary mixers, but only to such in which a part of the compounds of pig iron are to be subjected to an oxidizing treatment. However, in this case we have here a greater depth of the bath, therefore all dimensions should be based on the surface and not on the weight of the charge.

In this connection reference may be had to some tables of dimensions of European and American open-hearth furnaces published in *Stahl und Eisen* Jan. 12, 1910.

Notes on Chemistry and Metallurgy in Great Britain.

(From our Special Correspondent.)

The Corrosion of Metals.

If the conclusions arrived at by Messrs. W. R. DUNSTAN and J. R. HILL in their papers recently read before the Chemical Society (Journ. Chem. Soc., 1911; pp. 1835-1866) on "The Aerial Oxidation (Rusting) of Metals" and "The Passivity of Iron and Certain Other Metals" are to be accepted, then both the carbonic acid theory and the electrolytic theory of corrosion are untenable.

The authors had previously maintained (Trans. Chem. Soc., 1905, 87, 1548) that the presence of carbonic or any other acid is not essential to the rustings of iron and that the necessary conditions are only iron and dissolved oxygen—a view confirmed by Tilden (Trans. Chem. Soc., 1908, 93, 1356)—and held that the rusting of iron involves the intermediate formation of hydrogen peroxide, just as with other metals; but they now find that there are some substances which decompose hydrogen peroxide, but do not inhibit rusting, and therefore admit that this explanation is not entirely satisfactory or complete.

The advocates of the electrolytic theory explain the fact that pure iron may be kept immersed in pure water for months without change by assuming polarization of the iron by the hydrogen liberated as a result of ferrous ions and hydroxyl ions forming ferrous hydroxide; oxygen would then act as a depolarizer and the process would continue.

The authors object that iron would not become permanently polarized until the water were saturated with hydrogen; that iron can remain in boiling water for long periods without oxidation; and the retention of a film of hydrogen in boiling water is hardly an admissible supposition; that iron cannot facilitate the direct oxidation of the hydrogen by dissolved oxygen because the film of hydrogen keeps the metal from contact with the water; that if dissolved oxygen can depolarize iron, other depolarizers, such as potassium bichromate, chlorate and nitrate should do the same, but they do not; that the electrolytic theory does not explain the action of inhibiting agents other than the alkalis, viz., potassium chromate, bichromate, iodate, ferrocyanide and hydrogen peroxide, which all inhibit rusting, whilst the electrolytic theory demands that most of them should assist rusting by depolarizing the iron.

The authors determined the question of the solubility of iron in pure water with a negative result, and made many experiments on the cause of the action of inhibiting agents, the passivity induced by such agents, passivity and rusting, the

comparison of the oxidation of iron with that of other metals, and the formation of hydrogen peroxide during the rusting of iron.

Their conclusions from the investigations described in the first paper are: That existing theories do not adequately explain how inhibiting agents prevent rusting; but the fact that all these agents make iron passive and that the passivity persists after removal from the solution which caused it, does afford a satisfactory explanation.

The mechanism of the process of rusting of iron presents no essential difference from the aërial oxidation of other metals; traces of hydrogen peroxide are formed when iron rusts just as in the case of other metals, but the hydrogen peroxide is more probably the result of a secondary reaction than an intermediate product of the main reaction, since oxidation can apparently continue without its formation.

The aërial oxidation of metals results from the direct action of dissolved oxygen. In the case of iron ferrous hydroxide is first formed and is further oxidized to the ferric state. Iron does not pass into solution before rust is formed. The action of carbonic or any other acids is independent of the main process of rusting, which proceeds in their absence. The fact that iron which has been treated with inhibiting agents rusts when exposed to carbonic acid is due to the destruction of passivity by the carbon dioxide.

The Nature of the Passive Condition.

In the second paper the same authors give details of experiments on the production and destruction of the passive state in iron, zinc, magnesium, copper and lead. In the case of iron the theory that the passivity is due to a gaseous film was disproved by heating in a vacuum to 400° C., when the passive condition was not affected; but on heating in an atmosphere of hydrogen at 250° C., the temperature at which the magnetic oxide of iron is reduced, the passive condition was removed. This goes far to prove the correctness of the old view that the passive state of iron is due to a film of ferrosoferric oxide.

The authors find a difficulty in explaining the action of alkalis in causing passiveness, and yet state that it is known that under certain conditions iron can be oxidized by alkalis with production of a visible film of oxide. In the case of copper, the protective film has a red shade and probably consists of cuprous oxide. The film is non-metallic because it resists amalgamation of the copper by mercury.

The Value of Mechanical Tests.

Mr. C. E. Stromeyer, chief engineer of the Manchester Steam Users' Association, in his annual memorandum, gives some interesting details of experiments carried out on samples of fractured boiler plates. The results of the applied mechanical tests lead him to the conclusion that, except in cases of bad heat-treatment, none of these tests will distinguish between reliable and unreliable steel, and that chemical analysis, particularly the determination of phosphorus and nitrogen, affords the only available index when the nature of the raw material and the process of manufacture are not known. He expects that engineers will, nevertheless, not be inclined to rely much on chemical analysis which they cannot check, but will continue to prefer procuring boiler plates from makers of known reputation and applying the usual mechanical tests.

In view of the fact that the micro-structure often discriminates between good and bad steels of almost identical chemical composition, the author's statement that chemical analysis is the only guide is not likely to find a wide acceptance.

The Action of Caustic Soda on Boiler Plates.

In the same publication Mr. Stromeyer calls attention to the deleterious action of caustic soda solution on mild steel boiler plates when the density of the liquor exceeds 9 deg. Twaddell (sp. gr. 1.045, corresponding to about 4 per cent of NaHO at 15° C.) and the steel is in a state of tension. He advises that the concentration of caustic liquid in closed boilers under pressure should be avoided except for very weak solutions.

The Deflocculation of Clay.

Dr. E. G. Acheson presented a paper on "Deflocculation" before the London Section of the Society of Chemical Industry, which was received with very great interest, not only because of the desire to hear the distinguished author, but also of the interest of the subject itself. Dr. Acheson said that the unsuitability of American clays for binding material for graphite caused him to investigate the nature of the difference between sedimentary clays, such as those imported from Europe, and residual clays. After trying the effect of various solutions of organic substances he found that gallotannic acid, in dilute solution, materially reduced the quantity of water required to produce a given degree of fluidity with the clay and increased the tensile strength and plasticity. Investigation showed that the clay abstracted tannin from the solution. Briquets made from the treated clay had a strength more than 200 per cent greater than that of briquets of the original clay. Aqueous extract of straw had the same effect as gallo-tannic acid solution. Microscopical examination proved that clays treated with these substances became deflocculated, and the method of deflocculation was applied to graphite with the result that two new lubricants, "aquadag" and "oildag," were produced, consisting of deflocculated Acheson graphite suspended in water and oil respectively. The deflocculated graphite was found to be in a truly colloïdal state, and the size of the particles was estimated at 75 millionths of a millimeter, or 3 millionths of an inch. Acids, alkalis and salts caused aggregation of suspended deflocculated particles; and this might explain the formation of mud-banks at the mouths of rivers.

The Volume Relations of White and Grey Cast Iron.

The well-known superiority of grey iron castings compared with those of white iron has led E. Rosenberg (*Stahl. und Eisen*, 1911, 31, 1408) to investigate the relations between the volumes of the two kinds of iron on cooling from the liquid state to 1000° C. and at 0° C. Two methods of calculation were employed and gave concordant results showing that the volume of the grey iron expanded on solidification, whereas the volume of the white iron diminished, and that the expansion of grey iron increased with the percentage of graphite. Two specimens of grey iron both had a sp. gr. of 6.89 when liquid, 6.75 and 6.46 at 1000° C., and both 7.1 at 0° C. Two specimens of white iron also had a sp. gr. of 6.89 in the liquid state, 7.22 and 6.91 at 1000° C., and both 7.6 at 0° C. Pig iron with 3 per cent graphite and 1 per cent combined carbon gave for sp. gr. 7.1 liquid, 6.9 at 1000° C. and 7.2 at 0° C.; another pig with 1 per cent graphite and 2 per cent combined carbon had a sp. gr. of 7.1 liquid, 7.2 at 1000° C. and 7.4 at 0° C. The calculation for the last two sets of figures was based on the relative densities of pure iron, iron carbide and graphite, and the separation of graphite from carbide during solidification.

Engineering Imports and Exports.

The Board of Trade returns for the ten months ended on the 31st of October give the value of imports of iron and steel, including manufactured articles, as £9,109,220, an increase of £1,811,580 compared with the corresponding period of 1910; and exports £35,804,215, an increase of £132,763. Imports of other metals, including manufactures, were £22,976,488, a rise of £3,070,412; with exports £9,070,302, also a rise of £491,199. In electrical goods the imports reached £1,143,892 and the exports £2,286,868, both showing decreases of £167,287 and £994,036 respectively. Imports of machinery went up to £4,842,529, and the exports to £25,444,377, giving increases of £1,144,098 and £1,259,027 respectively. Imports of new ships are put at £60,093, and exports at £4,413,072; the imports showing an increase of £38,266, but exports are lower by £3,631,457. The figures for the month of October show that a satisfactory recovery is in progress from the depression caused by the recent labor

troubles; and, moreover, that the values of exports show considerable improvement on those for October of last year.

Market Prices.
November, 1911.

Copper has shown an upward tendency. Starting at £55.10.0 it has risen steadily throughout the month, closing at £58.17.6.

Tin has been, on the whole, ascending in price. Starting at £189 it dipped to £186.5.0 by the 3d, but afterwards rose to £198.5.0 (20th), and closes at £201.10.0.

Lead has risen a little. Starting at £16 it reached £16.2.6 on the 21st and closes at £16.3.9.

Haematite started rising decidedly on the 10th. Opening at 60/10, it rose to 61/10 on the 10th and 62/6 by the 21st, closing at 63/—.

Scotch Pig has been steadily increasing, with slight dip (6d) on the 17th. It opened at 52/3, rose to 53/4 by the 16th and 54/— by the 21st. It closes, however, at 53/9.

Cleveland has risen steadily, starting at 46/2, it reached 48/— by the 21st, and closes at 47/9.

India-rubber has remained steady. Opening at 4/3, it was at 4/3½ on the 8th and 4/3 on the 22d; closes at 4/4.

Alum, lump, loose, per ton	£5.12.6
Antimony, black sulphide powder, per ton	20. 0.0
Borax, British refined crystal, per ton	16. 0.0
Copper ore, 10 to 25 per cent, per unit	9/7 to 10.1½
Copper sulphate, per ton	20.15.0
Carbolic acid, liquid, 97/99 per cent, per gal	1.7
Camphor, 1 oz. tablets	1.9½
Caustic soda, ash 48 per cent, ordinary, per ton	5.10.0
Creosote, ordinary good liquid, per gal	3
Hydrochloric acid, per cwt	5.0
Mica, small slabs, original cases, per lb	6d to 2.0
Naphtha solvent, 90 per cent, 160° C., per gal	9
Platinum, per oz., nominal	9. 5.0
Petroleum, Russian spot	5¾
Quicksilver, per bottle	8.10.0
Sal ammoniac, lump, first, del. U. K., per ton	42. 0.0
Sulphate of ammonia, f.o.b. Liverpool, per ton	14. 8.9
Sulphur, recovered, per ton	5. 0.0
Shellac, Standard T. N. Orange Spots, per cwt	4. 4.0

Electrolytic Zinc Process in California.—From a statement of the Reed Zinc Co. of San Francisco we gather the following: "The Reed Zinc Co. is the result of the efforts of Frank A. Leach, former Director of the Mint, and his son E. R. Leach, the melter and refiner of the U. S. Mint at San Francisco." A site on the southwestern shores of the Bay of San Francisco has been chosen with ample railroad facilities. "The process by which the company proposes to handle ores is covered by patents of C. J. Reed and Carl Hering, and briefly stated consists of finely grinding and roasting the ore in a specially designed furnace, thus converting the metallic sulphides to a mixture of oxides and sulphates which are subsequently brought into solution. The zinc sulphate is separated, and the zinc reduced to metallic form by electrolytic methods. In subsequent procedure sulphuric acid and other valuable byproducts are recovered. . . . In the roasting process liquid sulphur dioxide and sulphur will be recovered." Mr. Reed is widely known as one of the founders of the American Electrochemical Society. We reserve discussion for our next issue.

Synopsis of Metallurgical and Chemical Literature

Iron and Steel.

Coke-Oven Gas and Tar Open-Hearth Furnaces.—In a discussion of a paper read by Dr Ing. Petersen, Dusseldorf, at the meeting of German Steel & Iron Masters (*Stahl und Eisen*, 1910, p. 80), Mr. Maltitz made the following remarks. He wondered whether the Hubertushütte was burning coke-oven gas in open-hearth furnaces successfully. He personally made tests along this line in the Dominion Iron & Steel Co., but with negative result. It was impossible to preheat the gas in regenerators, so the gas was burned directly like natural gas, flowing through 6" pipes. The heating effect was very low, therefore tar was also sprayed into the furnace by nozzles. The result of burning tar was not successful because the furnace roofs stood only 90 heats.

Mr. Amende of Hubertushütte replied that they had used coke-oven gas for two and a half years with great success, sometimes as much as 70 per cent of the coal being replaced by coke-oven gas. The durability of bulkheads and roofs decreased 8 to 10 per cent, but that of the checkers increased about 50 per cent. They ran 550-600 heats without repair work on bulkheads and roofs and as high as 1050 heats on the same checkers. The steel quality was not effected at all. In twenty-four hours, 1,800,000 to 2,600,000 cu. ft. of coke-oven gas were consumed, including iron and steel foundry's heating molds. The coal consumption per ton of steel was reduced from 31.8 per cent (1906) to 14.9 per cent (1909) by the use of coke-oven gas. A blast-furnace gas main is under construction, and it is hoped to further reduce the coal consumption by this means. The coking coal is of poor quality, so that only 45 per cent gas is available. The coke-oven plant contains ninety Otto-Hoffmann ovens with a capacity of 320 tons coal per twenty-four hours. The coke-oven gas analysis is: 6.5 CO_2, 1.2 O_2, 10.4 CO, 38.7 H_2, 16.4 CH_4, 24.8 N_2, b.t.u. = 377.

Different Types of Mixers.—The following details of various European mixers should be of interest: On the Julienhütte in Upper Silesia (*Stahl und Eisen*, 1910, page 2147) there is a 150-ton mixer, electrically tipped on rolls for six open-hearth furnaces at 40 tons each. The pig-iron inlet and slag-tapping opening are on one side, the tapping opening for pig iron on the other. The mixer is heated by producer gas, but has only air regenerators; the temperature inside is 2370° to 2550° Fahr. Coal consumption for 400-500 tons pig iron in twenty-four hours = 8 tons. The bottom is lined with magnesite.

On the Georgs-Marienhütte in Osnabrück (*Stahl und Eisen*, 1910, page 2151), there is one mixer for 150 tons and one for 250 tons for five open-hearth furnaces at 40 tons each. Pig iron is pre-oxidized in the mixer and this metal charged in the open-hearth furnaces. The mixer is on rolls; the bulkheads can be moved; all is done by hydraulic pressure. The gas for the five open-hearth furnaces is produced in nine Kerpely producers. The mixer is heated by blast-furnace gas from a 35.4-in. pipe line. The burning of blast-furnace gas is considered a secret, but it can be said that this gas burns with a high temperature. Blast-furnace gas is also used in the soaking pits and for some time it was used in open-hearth furnaces, but this was abandoned on account of the insufficient amount of gas. On account of pre-oxidizing in the mixer, the time for a heat in the open-hearth furnaces is considerably reduced, and two open-hearth furnaces now produce at least as much steel as three furnaces without mixer.

At Donawitz, Styria (*Stahl und Eisen*, 1910, page 21), there is a 150-ton mixer for twelve open-hearth furnaces of 30 tons each, heated by producer gas. There are twenty-five Kerpely producers furnishing gas to the open-hearth plant, to the ore-roasting and mill furnaces. Producer gas analysis: CO_2 = 2-2.5 per cent; CO = 30-31 per cent; H_2 = 12-14 per cent; CH_4 = 1 per cent. The bulkheads and roofs stood 583 heats; the checkers 3000-3600 (in 1908). Monthly production per furnace 3200 to 3400 tons.

Gold and Silver.

Available Calcium Oxide in Lime for Cyanide Process.—The almost universal use of lime as a means for maintaining protective alkalinity in cyanide solutions, and the fact that the percentage of calcium oxide contained determines its value, calls for quick and efficient means of estimating the quantity of calcium oxide in burned limestone. In the November, 1911, *Bulletin* of the Amer. Inst. of Min. Eng. MR. LUTHER W. BAHNEY presents a method which he has found to give quick and accurate results. A solution of oxalic acid is made, containing 14.6068 g per liter of water, and used to titrate the alkalinity of a weighed quantity of lime. In order that 1 cc of the oxalic acid solution shall be equivalent to 1 per cent CaO, he uses 650 mg of lime for each determination. This quantity is arrived at by the following proportion, in which x equals 650:

Lime	Lime	Oxalic	Oxalic
56.09	x	126.048	1.46068

The lime sample must be ground to pass a 200-mesh screen. Into a 300-cc Erlenmeyer flask place 50 cc distilled water, and add 650 mg of the sample to be tested. Stopper the flask and shake vigorously for 10 seconds; add two drops of phenolphthalein and then run in the standard oxalic acid solution until the pink color is discharged; then replace the stopper and shake. When the color returns, if it is due to lime it will be a bright pink, and perhaps 0.5 cc more solution will be required to finish the titration. But if the returning color is a weak pink, returning slowly, it indicates magnesia, and the lime titration may be regarded as finished with the first discharge of color. The mixture in the flask should be shaken frequently during the titration. The reading of the burette is the percentage of calcium oxide in the lime.

Slime Filtration.—The physics of slime filtration has been made the subject of an exhaustive investigation by GEORGE J. YOUNG, of Reno, Nev., his paper being published in full in the November, 1911, *Bulletin* of the Amer. Inst. of Min. Eng. After reviewing the various methods of filtering slime, and the physical condition of the material commonly called slime in the metallurgical industry, he describes experiments made to determine the effects of variations in pressure, temperature and physical composition of slime. Numerous curves and drawings accompany the paper. The author's comprehensive definition of slime is: A slime consists of a mixture of sands finer than 150 or 200-mesh screen, with an amorphous clay-like material, consisting principally of hydrated aluminium silicate.

Certain practical conclusions may be drawn:

1. The proportion of clayey material in ores which are subjected to all-sliming and filtration should be maintained at a minimum.

2. The slime pulp should be as free as possible from sands coarser than 150-mesh screen, and as large a proportion of the pulp as possible should consist of material passing a 200-mesh screen.

3. The slime pulp before filtration should be settled to as thick a consistency as possible consistent with ready handling by pumps and in pipes.

4. The temperature of the slime pulp should be maintained between 20° and 30°C. or higher.

5. The temperature of the wash water and the pulp should be the same.

6. Vacuum pressures should be varied until the proper intensity for the given slime is obtained.

7. Where very clayey slime is to be filtered, as much fine sand (limited as above stated) should be crowded into the pulp as it will carry without undue settling and clogging.

8. No. 10 canvas supported by slats gives the best all-round service for the thick cake, and No. 12 canvas on wire netting answers the requirements for the thin-cake filtering machines.

9. With slimes containing a large proportion of colloid or clayey material, pressures greater than those obtainable with the vacuum apparatus are of questionable advantage.

10. With slimes containing a large proportion of clayey material the vacuum filters should be used.

11. With slimes containing a small proportion of clayey material and much fine sand, both vacuum and pressure filters could be used with perhaps equally good results.

12. With slimes containing much coarse and fine sand the chamber filters with air agitation and high pressures would perhaps give the best results.

13. Of the vacuum filters the thin-cake continuous filters are a decided improvement over the thick-cake filters.

Parral Tank for Slime Agitation.—The Pachuca tank probably has become as widely known as any device used in the cyanide industry, and it has been accepted as few other devices have been. Some of its inherent weaknesses have been pointed out, but apparently without effect on its remarkable progress throughout the world. In view of these facts, more interest attaches to an invention known as the Parral tank, from its use in the Mexican district of that name. It is described by the inventor, BERNARD MACDONALD, of Pasadena, Cal., in a paper read before the San Francisco meeting of the American Institute of Mining Engineers. The Parral tank is in use at the mill of the Veta Colorado Mining & Smelting Company, Parral, Mexico.

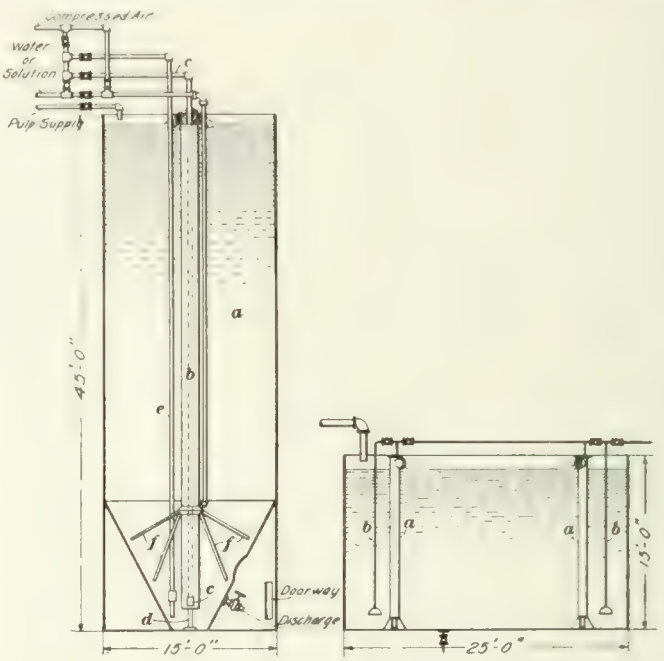

FIG. 1.—PARRAL TANK.

The dimensional relations of the Parral and Pachuca tanks are shown in Fig. 1. It will be seen that the objectionable height of the Pachuca tank is avoided in the low form of the Parral. In the Pachuca tank a definite ratio of height to diameter must be preserved, while in the Parral no cognizance of this ratio need be taken. At the Veta Colorado mill the Parral tanks are 25 ft. in diameter and 42 ft. in height, with a capacity two and one-half times as great as the standard Pachuca tank. For agitating the slime and raising it from the flat bottom to the top of the tank four transfer pipes *a* are installed, each 12 in. in diameter and set 12 in. from the bottom and 4 ft. from the tank side and equidistant from each other. In a tank of larger dimensions more transfer pipes would be needed. Compressed air is admitted to the bottom of these transfer pipes through a nozzle fitted with a ball valve which automatically opens and closes as required in the jet feeding of compressed air. This ball nozzle is a more efficient and satisfactory device than the elastic sleeve usually used on the bottom of the air pipe in the Pachuca tanks.

On the top ends of the transfer pipes are bolted tees of equal diameter, with the run in line with the pipes and the outlets so

directed as to discharge the pulp in line of segment cords to the circumference of the tank. The discharge of all the pipes being in the same direction, the force of the discharge sets up a spiral or rotary flow in the tank charge, which in a short time extends down to the bottom of the tank. This motion carries the particles round and round so that their length of travel before reaching the bottom of the tank is greatly increased over what it would be if the settlement were in a vertical line.

When Parral tanks are being filled the inflowing pulp is kept in agitation by means of compressed air admitted through auxiliary pipes shown at *b* in the figure. When the tank is filled to within 10 ft. or 12 ft. of the top the air is closed off the auxiliary pipes and opened on the air lift pipes.

The following table gives a comparative statement of the details of Pachuca and Parral tanks.

	Pachuca	Parral
Height in feet	45	42
Diameter in feet	15	25
Area of bottom of tanks, sq. ft.	176.7	490.8
Holding capacity for each foot in height, cu. ft.	176.7	490.8
Number of air-lift tubes	1	4
Diameter of air-lift tubes, in.	16	12
Cross-sectional area of air-lift tubes, sq. in.	201	452
Diameter of air pipe in lift tubes, in.	1.5	1
Cross-sectional area of air pipes in lift tubes, sq. in.	1.7671	3.1416
Proportional area tank bottom for each sq. in. of cross-section air-lift tubes, sq. ft.	.8	1.8
Area of tank bottom for each sq. in. of compressed-air pipe, sq. ft.	100	156

Cyaniding in Australia.—Milling and cyaniding on the Charters Towers gold field in Australia has been unfavorably criticized for excessive costs, which in the past have ranged from $1.75 to $3 per ton for milling (amalgamation and concentration), and from $1.50 to $2 per ton for cyaniding. In the October, 1911, issue of the *Mining and Engineering Review*, Melbourne, Mr. W. A. MACLEOD reviews the situation and shows that by improvement in the same old methods the costs have been reduced to $1 per ton for crushing, amalgamating and concentrating, and to $0.75 per ton. The author is of the opinion that the present costs could not be sufficiently reduced by new equipment to warrant the capital expenditure which would be necessary.

At the Brilliant Extended mill the ore is crushed by Blake crushers to about 1½-in. size and fed to Huntington mills and stamps. The Huntingtons are 5 ft. in diameter, running at 75 r.p.m., and fitted with 18-mesh screens. They crush 33 tons of hard quartz in 24 hours. The mills are economical in power, but expensive in maintenance, and their cost per ton exceeds that of the stamps by nearly 12 cents. The stamps weigh 1250 lb., have a 7-in. drop 103 times per minute, and crush 4.5 to 5 tons per stamp in 24 hours. Grading analyses show that the stamps crush finer than the Huntingtons, using the same screens.

The value of the ore ranges from $11 to $12.25 per ton. The tailing assays from 50 cents to 60 cents per ton. About two-fifths of the recovery is made by amalgamation, two-fifths by concentration and one-fifth by cyanidation. The concentrates are sold to smelters, as about $4.85 per ton more is realized in this manner than by local treatment with fine grinding, amalgamation and cyanidation.

The tailings from the concentrator are cyanided by percolation in tanks. Experiments have been made looking toward the agitation and filtration of the slime, but only a 55 per cent extraction was obtainable after four to five days' agitation. The old practice in treating the tailings was to spread them out to dry in the sun for some weeks, after which they were leached in tanks. This practice was expensive on account of the labor involved and the poor mechanical arrangements. It has been improved by first classifying the sand and slime in spitzkasten and then spreading the products separately. The sand dries rapidly, and the slime bed is dried more rapidly than before by breaking it up with disk harrows. When dry, the sand and slime are again mixed and ground, and filled into tanks by belt conveyors. The time of treatment is about five to six days; the value of the charge about $2.50 to $3, and of the tailing 40 to 65 cents. The tanks are discharged by sluicing, using 100 tons of water for 200 tons of charge. Precipitation of the gold solution is by zinc shavings.

Zinc, Lead and Copper.

Progress in Zinc Smelting.—In an advance chapter of "Mineral Resources of the United States," written by Mr. C. E. SIEBENTHAL, a number of improvements attempted are briefly described. The Saeger cleaning and charging machines are in use in Silesia. Mounted upon a truck in alignment with the sloping retorts are banks of screw conveyors. There are as many banks of conveyors as there are banks of retorts, and each bank contains from three to eight conveyers. After the condensers are removed, the cleaning machine withdraws the charge by inserting the screws into the retorts. Then follows the charging machine, which is similar in character, and which forces the charge into the retorts by means of screw conveyors. The advantages are: Saving of half the labor charge; shortening of the injurious cooling-off period while cleaning and charging; lengthening the time for distillation, and more healthful conditions of work.

Two forms of moving furnaces have been designed. The Wettengel rotatable furnace was described in this journal for April, 1911, page 198. The Hughes revolving furnace consists of a rotary retort contained in a rotary combustion chamber. The charge enters continuously at the upper end of the gently sloping retort, which discharges both residue and zinc vapor into a stationary cylindrical condenser at the lower end. The waste heat of condensation is used to preheat the charge. A retort 8 in. in diameter and 7 ft. long has a capacity of about 5 tons of roasted zinc concentrate in 24 hours. A commercial-sized retort is installed at the plant of the Hughes-West Continuous Zinc Distillation Company, Southampton, near St. Louis, Mo.

The Hopkins process of smelting zinc-lead concentrate in ordinary retorts consists in the use of a charcoal or carbon filter between the retort and condenser. Higher recovery and better grade of spelter are the improvements claimed for this process. In a nineteen weeks' comparative test at Swansea between ordinary condensers and the Hopkins condenser the latter gave 7 per cent greater recovery.

Sulman and Picard have patented a method of smelting very fine zinc-lead concentrate and slime by briquetting the roasted material with bituminous coal and pitch in the following proportions: Roasted ore, 70 per cent; bituminous coal, 25.5 per cent; pitch, 4.5 per cent. After retorting the briquets they are found to remain intact in a condition suitable for direct charging into a lead blast furnace. Experiments indicate that a recovery of 80 per cent of the zinc can be effected from this material, and that the retorts have an increased capacity of one-third, with a saving of time in charging and cleaning.

Electrostatic Separation.—At the mill of the Calumet & Sonora of Cañanea Mining Company, near Cananea, Mexico, Huff electrostatic separators are in operation on zinc-copper concentration middlings. The details of operation are given by Mr. J. N. HOUSER, superintendent, in the December, 1911, issue of the *Mexican Mining Journal*. The middling from the concentrator assays about as follows: Zn, 30 per cent; Cu, 6.5 per cent; Pb, 3 per cent; Fe, 10 per cent; Ag, 3 oz. per ton. The middling is dried and sized into three grades, 2 mm to 20-mesh, 20 to 40-mesh, and minus 40-mesh. The coarse grade is treated on a Huff standard machine, and the two finer grades on modifications known as the toboggan type, which was developed at the plant of the American Zinc Ore Separating Company, Platteville, Wis. The machines are charged with static electricity at

20,000 tons. The mill is now making a zinc concentrate assaying Zn, 52 per cent.; Fe, 3.5 per cent.; Cu, 0.8 per cent. A copper product also is obtained assaying Cu, 16 per cent; Fe, 22 per cent; Zn, 10 per cent; Ag, 10 oz. per ton.

A part of the material treated is from an old dump of accumulated middling which, by exposure to the elements, has caused a coating of copper to be deposited on the zinc, thereby destroying the natural difference in conductivity. In order to restore this difference, the middling is given a bath of cyanide solution which dissolves the copper film. It is then dried and treated as usual. The plant is handling 35 tons per 24 hours, and is run wih three men per shift. The cost is $1.20 per ton treated, but this cost will be reduced when fresh mill middling only is handled.

Recent Metallurgical Patents.

Iron and Steel.

Eliminating Occluded Slag.—Molten steel or iron, by whatever process prepared, usually contains small particles or globules of slag which, unless they be removed, impair the quality of the metal. For the purpose of accelerating the removal of these bodies, Mr. ROBERT LOCK, of Tarentum, Pa., proposes to tap the fluid metal from the furnace or converter into a ladle in the usual way, the slag being allowed to remain on top of the molten metal. From this ladle the metal is transferred in a thin stream to a second ladle, preferably by bottom pouring so that the supernatant slag cannot be included. At the same time varying amounts of lime or other reagent, preheated or not, are gradually added with the stream flowing into the second ladle. By thus causing the metal to flow in a thin stream, and to come in contact with the lime, the globules of slag are eliminated from the metal. The inventor claims that metal produced by this method has a high degree of purity and is less susceptible to electrolytic dissociation. (1,008,420, Nov. 14, 1911.)

Process of Treating Coke.—Owing to the presence of sulphur in coke usually used in melting iron ore or in melting iron in cupola furnaces, the molten product becomes contaminated with a percentage of sulphur which must subsequently be removed. To prevent the sulphur in the coke from uniting with the iron Mr. HARRY SPURRIER of Detroit, Mich., proposes to treat the coke with a substance with which the sulphur will more readily unite. Sodium carbonate is preferred as being a cheap substance soluble in water. He recommends that a solution of this salt be used to impregnate coke prior to its use in the furnace. When the coke is used a soda salt of sulphur will be formed as a slag which will contain not only the sulphur in the coke, but some of that in the original iron as well. Other salts of potassium and sodium can be used. (1,007,153, Oct. 31, 1911.)

Gold and Silver.

Slime Thickener and Decanter.—In the treatment of slime in the cyanide process, some means of thickening the pulp and decanting clear solution is quite essential. Fig. 1 illustrates a form of thickener designed by Mr. MARK R. LAMB, of Milwaukee, Wis., similar in some respects to the design of the Dorr machine. It consists primarily of a flat-bottom tank 15, with an inlet for slime pulp at 1, and a circular launder 3 and spout 7 for the discharge of clear solution. The device for drawing thickening pulp to the central bottom of the tank consists of four radial arms 12 provided with blades 14. These are made to revolve by means of a driving mechanism placed beneath the tank, in which a worm 20 drives a gear wheel 19 attached to a vertical shaft 91 on which is keyed a frame 17 extending upward into the tank. The frame is perforated at 16, just inside the tank, for the purpose of allowing the thickened pulp to enter the bottom of the pipe 6 which is connected with a diaphragm pump 4, which removes the thickened slime as fast as the revolving arms and blades deliver it to the center of the tank. Provision is made to raise the arms 12 so that their position may be regulated with respect to the thickness of the layer of material at the bottom of the tank. (1,008,234, Nov. 7, 1911.)

A device similar in purpose to other thickening machines, but having in combination means for elevating the thickened slime or washed sand to another tank for further treatment, is shown in Figs. 2 and 3. Fig. 2 is a part sectional elevation of the invention, showing a tank and attached elevating means. Fig. 3 is a view of the screw conveyor as seen from above and at right angles to Fig. 1. The invention is that of ALEXANDER

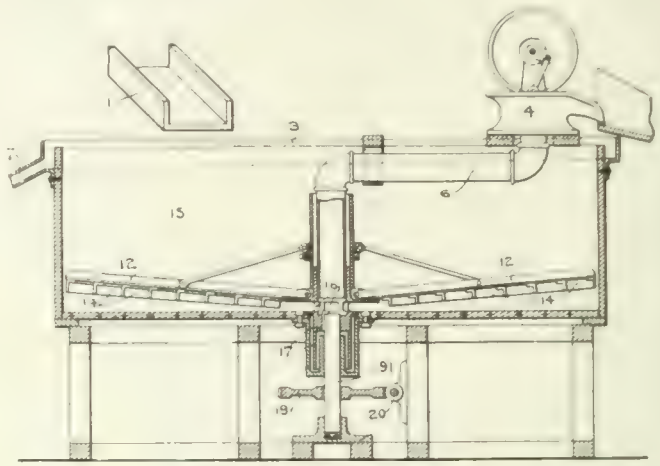

FIG. 1.—SLIME THICKENER.

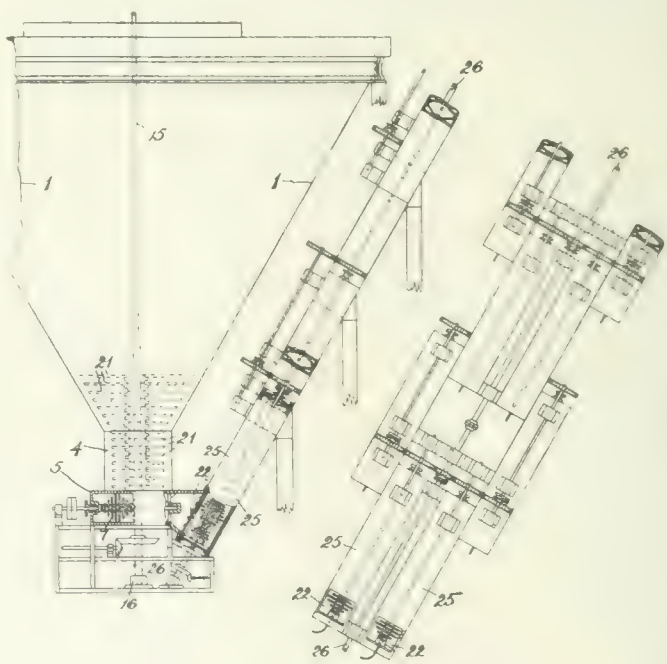
J. ARBUCKLE, of Johannesburg, Transvaal, South Africa. Referring to the figures, 1 represents a settling tank having a lower cylindrical portion 4 connected with a box 5 in which intermittent or continuous helical feed conveyors 7 are placed. By means of openings 22 in the frame between the box 5 and the inclined screw conveyors 25, thickened pulp can pass to the



FIGS. 2 AND 3.—SLIME THICKENERS.

latter for elevation. In the tank 1 is a vertical shaft 15 running in a step bearing 16, with radial arms 21 attached in the form of an intermittent helix or screw thread. In operation these radial arms force the slime or sand downward into the box 5, whence it is driven by the screw 7 into the inclined screw conveyors 25. It will be observed that the screw conveyors are arranged in sections or lifts and that the slime delivered at the top of one section is raised in the next, and so on. One drive

shaft 20 serves for the operation of all the screw conveyors, suitable gearing being arranged as shown. The inventor's idea in arranging the inclined conveyor in sections was to avoid the difficulties in driving long screw conveyors, and to provide for intermediate supports in its length. (1,008,513, Nov. 14, 1911.)

Electrolytic Amalgamation.—For the recovery of finely divided gold, silver or platinum occurring either in native sand or finely ground rock, electrolytic amalgamation has offered hope to many inventors. It has been pretty clearly demonstrated that in its application to plates electrolytic amalgamation has failed to produce any good results. With the use of mercury riffles or wells, however, it has seemed possible to secure better results. In Fig. 4 we illustrate a device of JAMES H. ALLING, of Columbia, Cal., designed to use electricity in connection with amalgamation on plates and in wells or riffles.

In the drawing, 24 represents a pipe and valve controlling a flow of sand and water or other material containing finely divided gold. 32 represents a pipe and valve from which a solution of potassium cyanide, mercuric chloride, or other similar substance can be added to the flow of pulp for the purpose of

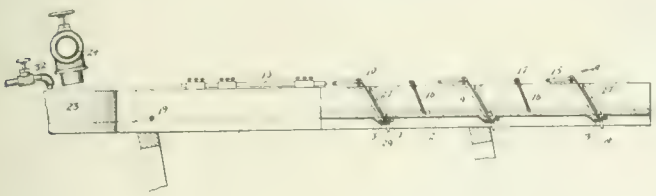


FIG. 4.—ELECTROLYTIC AMALGAMATING APPARATUS.

accelerating the amalgamating action by cleansing the gold. The sluice box is indicated at 1, and the plate at 2, with depressions or mercury wells at 3. The plate is continuous and is connected at cathode. Adjustable anode amalgamating plates are placed at 9, extending to within ⅜ in. of the surface of the mercury, and, in addition, there are swinging carbon anodes 16 at intervals above the plate.

About 4 tons of water are used per ton of sand, and the quantity of cyanide and mercury solution used is proportioned to the value and condition of the sand. The inventor has found that from ½ lb. to 1 lb. of cyanide and 2 oz. mercuric chloride in 5 gal. of water gives good results when introduced in the proportion of 1:1000 or 1:2000 parts of sand pulp. The electrolysis of the cyanide and mercury solution cleans the gold and facilitates amalgamation. A current density of 1/10 amp to 1 amp per square foot of cathode surface is used according to the value of the ore. Five volts are found to be satisfactory in practice. The inventor claims to have recovered and saved over 95 per cent of the value of the material which could not be saved by ordinary processes.

The surface of the anode is amalgamated in order to replenish the aqueous solution of mercuric chloride, and in order further to keep the anodes supplied with mercury the inventor places a plate 27 in front of each anode, a cup being formed at the top which is kept filled with mercury. As the anode plates are perforated with fine holes, the mercury finds its way through them onto the surface exposed to the flow of sand and solution. A suitable mercury trap is used at the end of the plate to catch particles of mercury that may be washed out of the sluice. (13,307, reissued Nov. 7, 1911.)

Zinc and Copper.

Preparation of Oxide of Zinc for Smelting.—The oxide of zinc obtained by precipitation from solutions of zinc salts, or from the condensation of zinc fume is usually so light and bulky that it is not regarded as a suitable substance for smelting. It is the object of an invention of Mr. R. W. E. MACIVOR and WOLDEMAR HOMMEL, of London, England, to overcome this difficulty by producing dense zinc oxide. The process consists in mixing the oxide with zinc chloride substantially in proportions to form an oxy-chloride of the formula $ZnCl_2 . 6ZnO$. This compound has the property of setting, like cement, into a dense solid, from which the zinc chloride can be volatilized at a temperature of 300° C. to 400° C., and collected for further use. The dense oxide remaining is then in suitable condition for smelting. A modification of the process consists in mixing carbonaceous material with the oxide and zinc chloride, so that after the mass sets and the chloride has been driven off the portion remaining is immediately ready for smelting by heat or electricity. The porosity of the carbonaceous mixture is an aid in driving off the zinc chloride, as well as in the subsequent reduction. If desired, the carbonaceous mixture could be molded into any convenient form so that after expulsion of the zinc chloride it might be used as electrodes in an electric furnace. Strong zinc chloride liquors can be utilized by precipitating zinc oxide from, say, six-sevenths of their weight and adding the oxide thus produced to the other one-seventh, which would be the requisite quantity to form the oxy-chloride. The density of the oxide formed in the manner described is in some cases twice the original. (1,007,124, Oct. 31, 1911.)

Briquetting Copper Shavings.—According to the invention of Mr. MAX GLASS, of Vienna, Austria-Hungary, metals containing copper, such as shavings and the like, can be briquetted by the use of cupric oxide as a binding agent. If the particles to be briquetted are not already covered with a coating of oxide, they may be heated to 100° C. and thus coated. By treating the mass with ammonia, the cupric oxide forms cuprammonium or ammonical cupric oxide, which diffuses throughout the mass. On pressing and heating, the cuprammonium is decomposed and the cupric oxide deposited uniformly on the surface of the metal where it forms a good cement for the material to be briquetted.

Ammonium carbonate may be used instead of ammonia, a 3 per cent to 6 per cent solution being employed. Quicklime is then added to the treated mass and the briquettes exposed to air after being pressed. The mass heats owing to the slaking of the lime; ammonia is formed which combines with the cupric oxide and diffuses throughout the mass, being subsequently decomposed by the heat of the slaking lime and leaving cupric oxide uniformly distributed over the surface of the particles in a manner favorable to binding the particles together. (1,008,254, Nov. 7, 1911.)

Manganese and Calcium Fluoride.

The process of producing metallic manganese and calcium fluoride by the reduction of manganese fluoride with calcium carbide has been patented by WALTER S. ROCKEY and HILLARY ELDRIDGE, of New York. In a refractory crucible lined with magnesite they place a mixture of manganese fluoride and calcium fluoride, the latter acting as a flux, and fuse the same. Into the fused bath they add a proportionate amount of calcium carbide and continue to heat with exclusion of air. Metallic manganese is reduced and settles to the bottom of the crucible, while the liberated carbon from the carbide floats on top of the molten mass. The reaction is expressed as follows:

$$CaC_2 + MnF_2 = CaF_2 + Mn + 2C.$$

Metallic calcium can be used, but the carbide is preferred on account of the violence of the reaction when calcium is used. (1,007,734, Nov. 7, 1911.)

Roasting Furnace.

Thomas Edwards, of Ballarat, Victoria, Australia, has recently been granted letters patent on an improvement in his roasting furnace, which is of that type in which a series of rotary rabbles is used to stir the ore and advance it from one end of the hearth to the other, owing to the arrangement of the rabbles by which their paths of rotation intersect. The improvement consists in construction which permits the use of the furnace as a combined reverberatory and muffle furnace, or as either reverberatory or muffle furnace only. A cooling hearth also is provided for the discharged roasted ore, on which the same mechanism of intersecting rotary rabbles is used to stir and advance the ore. (1,008,892, Nov. 14, 1911.)

New Electroplating Dynamo.

A new low voltage dynamo for electroplating and electrolytic work has just been brought out by the Munning-Loeb Company, of Matawan, N. J., under the trade name "Optimus dynamo" (Fig. 1).

Except in the smaller sizes, Optimus dynamos are of the multipolar type in order to secure as good a magnetic distribution and as high an efficency as possible.

As Fig. 2 shows, the Optimus dynamo gives a practically constant voltage from no-load to 25 per cent overload. This remarkable constant line voltage is automatically maintained by means of a special compound winding, without any manual operation of field rheostats. This straight horizontal voltage characteristic makes it possible for the plater to throw different tanks in and out of the circuit at will, without having to worry about the effect on the voltage of the dynamo. There is thus never any danger of burning the edges of the work due to short periods of high voltage.

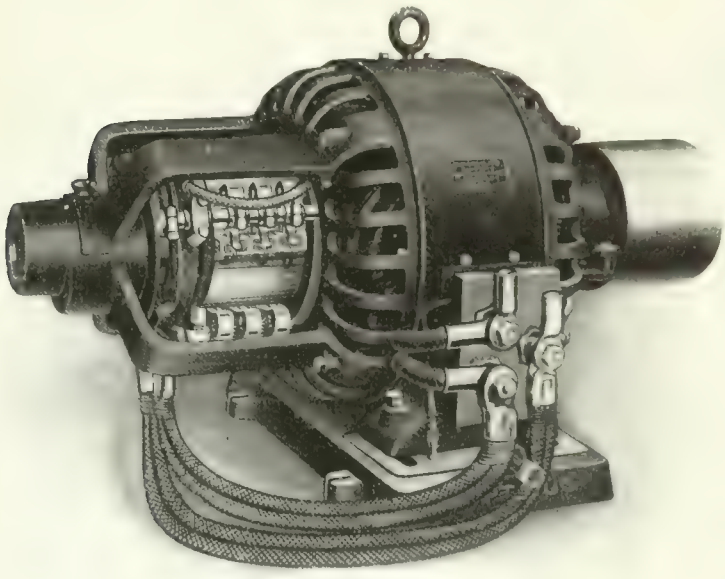

FIG. 1.—ELECTROLYTIC DYNAMO.

Test curves of this generator are also shown in Fig. 2.

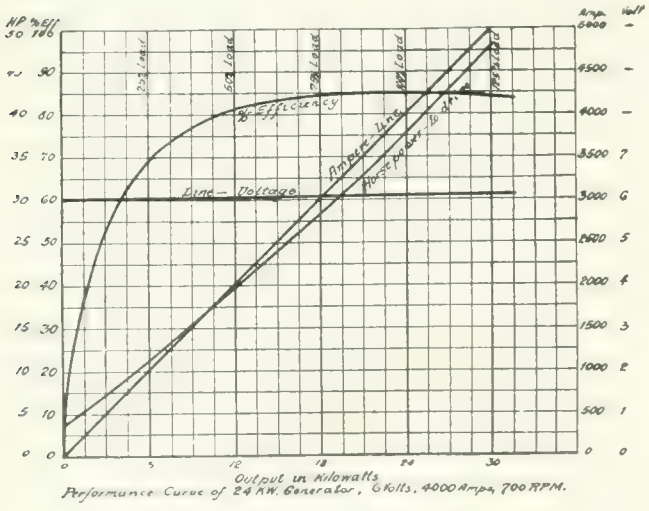

FIG. 2.—TEST CURVES OF ELECTROLYTIC DYNAMO.

The compound winding also maintains a fixed neutral position for the brushes on the commutator so that sparkless commutation is secured without shifting of the brushes with changes in load.

The brushes are made of a special carbon compound and are held against the commutator by means of an adjustable steel spring. A flexible braided copper cable carries the current away from the brushes. These brushes bear radially upon the commutator and it is claimed that they can be used for their entire length and that they will not score or cut the commutator. Furthermore, the fact that the carbon brushes bear radially insures that they will always remain at the neutral point.

The Optimus plating dynamo is built for either two-wire or three-wire circuits in all sizes from 300 watts to 50 kilowatts.

The manufacturers of the Optimus dynamo are also making a special feature of their direct-connected sets, and can supply any size of plating dynamo directly connected to any type of alternating current or direct-current motor, mounted on the same bed plate.

These dynamos are provided with an efficient system of ventilating and the usual guarantee is given that "no part of the machine will have a temperature greater than 45° C. over that of the surrounding atmosphere when the machine is operating continuously at proper speed at full load," although it is claimed that the actual temperature rise given under test is far below the 45° C. quoted in the guarantees.

Alloy Steel Standards.

As a result of the great increase in the use of alloy steels in recent years many chemists whose experience in alloy-steel work has been limited are now being called upon to analyze alloy steels and thus has arisen a decided want for standards which could be relied upon as positively correct.

To meet this requirement, the Scientific Materials Company, of Pittsburgh, Pa., has put on the market four different alloy standards (chrome-vanadium, vanadium, nickel and tungsten steel).

These standards have been checked by seven of the best-known alloy-steel chemists in the Pittsburgh district. The following methods were used.

For chromium: oxidation with potassium permanganate in a sulphuric acid solution, oxidation with potassium chlorate in nitric acid solution, and Blair's method from sodium hydrate precipitate.

For vanadium: Johnson's method by using an internal indicator, Blair's method, and colorimetrically with hydrogen peroxide.

For nickel: potassium cyanide titration and precipitation with dimethylgloxime, and the ether separation method.

For tungsten: by evaporation with hydrochloric and nitric acids.

The analysis of the standards are as follows: The results given are averages of the different determinations and were compiled by Mr. N. B. Hoffman, chief chemist of the Colonial Steel Company.

Chrome-vanadium steel standard (basic open hearth): 0.34 per cent C, 1.06 Cr, 0.16 V.

Vanadium-steel standard (crucible): 0.82 C, 0.228 V.

Nickel-steel standard (basic open hearth): 0.335 C, 3.40 Ni.

Tungsten standard (crucible): 1.25 C, 2.37 W.

Deflocculation.—In a paper read recently in London by Dr. E. G. Acheson before the Society of Chemical Industry the author gave an interesting account of his deflocculated graphite and its uses in oildag and aquadag. Some information given in the conclusion of his address concerning the size of the deflocculated graphite particles which were stated to approach molecular size, was particularly interesting. According to Mr. Jerome Alexander, who examined them by the ultramicroscope, the particles are in rapid motion and of a size estimated as 75 millionths of a millimeter, or 3 millionths of an inch, whereas particles of ordinary finely disintegrated graphite are 1000 times as large.

Uses of Bakelite for Acid-Proof Linings and Other Chemical Purposes.

The General Bakelite Company, 100 William Street, New York City, is putting on the market a great number of varieties of special bakelite raw materials, each one intended for a distinct purpose.

The technique of bakelite varies so much with the condition and with the purposes in view that it is practically impossible to give a general method of working. For instance, the methods used for making molded articles are very different from those which consist in applying liquid bakelite A on the surface of vessels or machinery which have to be protected against the action of chemicals. Then again, the use of bakelite, where high dielectric properties are required, is totally different from those where strength and ease of manipulation are paramount considerations.

For the latter purpose two new varieties of liquid bakelite A have recently been put on the market and a description of these will certainly interest our readers.

These two new varieties (liquid bakelite A10 and liquid bakelite A15) are specially intended for making acid and solvent-resisting linings. They are also very useful as a cement or glue, for instance, in the manufacture of brushes, or for gluing wood, or for applying wood veneer on wood, metal or stone.

The main difference between A10 and A15 is that the former is made with purer materials and has a somewhat greater tensile strength. However, for most purposes, the cheaper variety, A15, is satisfactory. Neither is intended for electrical purposes for which other liquid and solid varieties, bakelite varnish, etc., are specially prepared with a view of high dielectric strength.

The main characteristics of liquid A10 and A15 are the following:

They gelatinize after being heated for a while at a temperature of 75° to 80° C. (167° to 176° F.). If heating at this temperature be continued for several hours a very hard transparent mass of solid bakelite C will be the result. This hardened product will withstand most chemicals and solvents. The process of hardening can be considerably hastened by increasing the temperature after first solidification has set in. The temperature can thus be raised to 90°, 100°, 110° and 120° C. (195°, 212°, 230°, 248° F.) and over, and the hardening process takes relatively little time. Special attention should be paid to the fact that if the temperature be raised too rapidly the mass may become porous.

Liquid A10 or A15 can be spread on a warm piece of wood and heated in a drying stove at temperatures below 100° C. (212° F.) and thus hardened to a very hard brown-red enamel-like coating, which can be sand-papered, polished and finished in the usual ways.

For certain purposes a better coating can be built up by applying a first layer, which after hardening, sand-papering and polishing, is finished by the application of a very thin layer of bakelite lacquer, and then by submitting it to a final baking.

If suitable pigments, for instance, lamp black, vermilion, chrome green, or aniline dyes be added, several suitable colors may be developed at will.

Pieces of wood or metal may be glued together by means of liquid A10 or A15. In this case, the liquids are simply applied as if they were glue. The glued surfaces are kept in contact by means of clamps or other means of establishing gentle pressure, while the objects are heated, either in a baking oven, or any other suitable device.

Here again, the hardening can be carried out at temperatures as low as 75° to 80° C. (167° to 176° F.), and these are the temperatures which should be preferred for objects which can not well stand higher temperatures; but in that case the hardening process is necessarily slow. In all cases where the objects can stand higher temperatures it will be preferable to use the latter and thus shorten the whole process.

Whenever liquid A10 or A15 is used as a glue or as a cementing material it will be found advantageous to incorporate with the same some filling material, for instance, finely ground silex or finely ground sand. If liquid A10 or liquid A15 be mixed with a sufficient amount of short asbestos fiber or clay a paste can be obtained which can be kneaded and worked by hand. Such pasty mixtures can best be made in a sausage machine, meat chopper or other kneading device.

The proportions of filling material and of liquid A vary according to the nature of the filling material and to the consistency of the paste which is desired; this can easily be regulated by increasing the relative amount of either one of the constituents until the mass has the proper physical qualities.

In this way a paste can be made of about the consistency of bread dough, which can easily be applied as a putty or rolled into sheets, and the latter can be applied on metallic surfaces, or can be used to line metallic vessels with a protective coating, which will make them withstand better the action of chemicals or solvents.

The following examples of pasty mixtures may serve as a guide:

1. One part by weight of very short-fiber asbestos and one part of liquid A10 or A15.

2. One part by weight of long-fiber asbestos and one part of liquid A10 or A15.

3. One part by weight of short-fiber Sal Mountain (amphibole) asbestos and one part of liquid A10 or A15.

4. One part by weight of finely ground wood-flour and three parts of liquid A10 or A15.

Pasty material, made as described above, if heated at temperatures of at least 75° to 80° C. (167° to 176° F.), will stiffen by and by to a very hard mass which can be sawed, filed or drilled. The hardness of the mass depends, first of all, on the temperature at which it has been heated.

The temperature of 75° to 80° C. (167° to 176° F.) is considered as minimum temperature, but it is much preferable if heating can be carried at higher temperatures, for instance, 120° C. (248° F.) or over. At the latter temperature the hardening occurs very rapidly and may be finished within one hour, sometimes less. The very best results are obtained by starting at a low temperature and rapidly but gradually increasing this temperature as soon as hardening has set in. Too rapid heating may cause porosity.

The amount and the quality of the filling material has very much to do with the ultimate hardness of the mass; for instance, with long-fiber asbestos the mass will be less brittle than if short-fiber or powdered filling materials be used. The use of relatively long-fiber asbestos gives a very tenacious mass, which can be cut by means of a knife and which withstands shock impacts better. If instead of asbestos clay or slate dust be used the mass will be harder but more liable to break on impact.

In the same way asbestos may be replaced by other fibrous materials, as, for instance, finely ground sawdust or wood-flour. In the latter case the coating will not stand temperatures above those at which wood is decomposed by heat.

For certain purposes where lightness and a certain resiliency are required, finely ground cork, or mixtures of cork and sawdust or wood flour, make an excellent filling material.

Liquid A10 and A15 keep pretty well at ordinary temperatures, although after some months they may thicken somewhat, especially if kept in warm rooms. In the same way a paste made up as described above will keep well for several days and will not acquire its final hardness until it has been heated.

In cases when before hardening by means of heat the paste has become too stiff it can be softened again by addition of fresh quantities of liquid A. Further, liquid A10 or A15 which has become too thick by age can be thinned to the proper con-

sistency by adding some alcohol; but the addition of alcohol and similar solvents will exert a retarding action on the hardening process when heat is applied. So after these solvents have once been added it will be found necessary to heat at decidedly higher temperatures in order to produce maximum hardness.

Liquid A10 and A15 can be diluted with a certain amount of water. For instance, liquid A10 when fresh can take up as much as 1½ times its own volume of water; later on when the product is older and thicker, the amount of water which it can take up becomes considerably less. This singular property of being able to take up water offers a means for diluting the material in case very thin mixtures are wanted.

It should be noted that liquid A15 takes up considerably less water than A10, so that in this case water has to be added with more precaution and more sparingly. At any rate, whenever it be found desirable to add water, the addition of the latter ought to be done carefully while stirring, and no more water should be added than what will give a transparent solution. The addition of more water will cause a white precipitate, and a separation of the mass into a thick, viscous, white, grayish substance.

Liquid A10 or A15, exposed to the air, develops a dark red-brown color, which is very characteristic.

As already stated, the pasty mixture of liquid A10 and A15 can be used as a cement or as a packing material. If it be applied to a hot steam pipe it will soon harden to the point where it only can be detached by means of a chisel.

It also can be applied so as to protect from corrosion metallic vessels or metallic machinery submitted to the action of chemicals. The application is easily made by rolling the paste out in sheets of about a quarter of an inch thick or more and applying these sheets to the metallic surfaces which have to be protected, then baking the whole in an oven with the precautions as described above, until the mass has been transformed into the final condition of maximum hardness.

For such purposes it is always better to apply the material in not too thin layers because it is very difficult to spread a thin film of any material so uniformly that there should not exist some unprotected places where corrosion can occur.

For certain chemical uses like digesters the possibility of chemical corrosion is augmented by mechanical abrasion due to the friction of moving liquids or solids. For such purposes there exists a simple and efficient way for lining the vessel with acid-proof bricks held together with bakelite cement.

This is accomplished in a somewhat similar way as porcelain-lined ball mills are made, with the difference that the walls of the vessel ought first to be lined with a thin sheet of asbestos paper, impregnated with liquid A; on this the brick lining is inserted and fastened with a mixture of liquid A and some inert filling materials like clay baryta, or powdered silex, or asbestos. This liquid mixture is easily applied and then a suitable heater, for instance a gas stove, is introduced in the vessel so as to raise the temperature of the lining to at least 80° C. (176° F.), or higher, until the polymerization into bakelite C has taken place.

Whenever asbestos is used as a filling material it should not be forgotten that Canadian asbestos is easily attacked by acids. Amphibole asbestos is considerably more resistant to acids; unfortunately it lacks strength and fibrous qualities. Green Cape asbestos resists acids sufficiently well and has a good strong fiber, but it is more expensive.

Coal Age is the title of a new weekly devoted to coal mining and coke manufacture and published by the Hill Publishing Co. The first issue appeared on October 14. The issues so far received show that the field is broadly covered both as to the technical problems and commercial news. An interesting new feature is the sociological department. We cordially wish our contemporary a long and successful career.

The Electric Furnace for Small Steel Castings.

Neglecting malleable, semi-steel, and other kinds of castings masquerading under the good name of steel castings, there have been in the United States until recently only three processes for the manufacture of steel castings.

All specifications to date call for steel castings to be manufactured by one of the following processes: crucible process; Tropenas or similar processes; open-hearth process.

It is quite usual to divide commercial steel castings into three grades, viz.: soft, medium and hard. The chemical characteristics corresponding to these three grand divisions are in general as follows:

	Soft.	Medium.	Hard.
Carbon	0.10-0.20	0.20-0.35	0.35-0.50
Manganese	0.20-0.85	0.20-0.85	0.20-0.85
Phosphorus, not over	0.05	0.05	0.05
Sulphur, not over	0.05	0.05	0.05
Silicon, not over	0.40	0.40	0.40

The corresponding physical characteristics when the steels are properly annealed are as follows:

	Soft.	Medium.	Hard.
Tensile strength, minimum, in lbs. per sq. in.	55,000	65,000	80,000
Yield point, minimum, in lbs. per sq. in.	27,000	31,000	38,000
Elongation, per cent	22	18	15
Reduction, per cent			20
Bending test	120°	90°	Slight

As a general proposition the essential characteristics of the majority of steel castings are as follows:

First.—Castings well cleaned, secured by sand blasting.

Second.—Solid castings, secured by proper gates and heads.

Third.—High yield point, approximating the ultimate strength, secured by soft or medium grade of castings.

Fourth.—A good bending test, secured by soft or medium castings.

Fifth.—Freedom from brittleness when cold, secured by low phosphorus.

Characteristics 1 and 2 are within the control of every foundry. Moreover, defects in these qualities can usually be detected by the consumer through surface inspection.

Qualities 3, 4 and 5 can only be determined by the consumer through laboratory tests, and, in the absence of such tests, by care in selecting the manufacturer and the process he uses.

Crucible-Steel Castings.

The manufacture of crucible-steel castings as practised in this country is purely a melting process, requiring little or no technical knowledge, as is evidenced by the rapid, almost mushroom growth in the number of plants throughout the country and clearly shown in the records of the advertising pages of technical journals.

Crucible-steel castings are, as a rule, made from punchings purchased in the open market. Unless careful analysis is made of each and every car bought, most varying results in the castings are apt to follow. In this process there is little or no change in the phosphorus and sulphur during the melting of the punchings. The percentages of silicon and manganese are more or less under the control of the melter. The increase in the percentages of carbon is the most serious drawback to this process; in general it increases about two-tenths of 1 per cent.

The average good crucible steel casting will analyze:

Silicon	0.25 to 0.50
Manganese	0.40 to 0.80
Phosphorus	0.025 to 0.040
Sulphur	0.030 to 0.040
Carbon	0.35 to 0.50

The percentage of carbon in the punchings *may* remain constant during the melting, if the raw material is melted most carefully in a clay or clay-lined pot. This is rarely or never done in commercial practice, owing to the added initial cost of the pots and the fact that they last for fewer heats than the regular graphite pots.

If punchings of the same analysis are melted in graphite pots, the resulting steel will vary from pot to pot, and will

also vary when melted in the same pot, depending upon how often the pot is used.

The change that takes place is well illustrated by the following actual test, which was an effort to make low-carbon steel castings, the material charged in the pot being selected muck bar:

Muck Bar.		Analysis of Casting.	
Silicon	0.21	Silicon	0.17
Manganese	0.00	Manganese	0.30
Phosphorus	0.264	Phosphorus	0.204
Sulphur	0.017	Sulphur	0.015
Carbon	0.00	Carbon	0.29

From what has preceded it is to be noted that commercial crucible steel castings (owing to high carbon content) come under the grade known as hard. They are usually difficult to machine and will stand little or no bending test. Due to the fact that the crucibles hold only 80 to 100 lb. of metal, more or less variation in the chemical and physical qualities is bound to result in a given lot of castings. While one casting may possess the desired qualities, a similar casting poured from the succeeding pot may be far below the standard.

Many consumers of small steel castings have purchased them from the foundries using the crucible process, under the false impression that they compared in quality with "crucible steel," otherwise known as "tool steel."

Tropenas Steel Castings.

The Tropenas, like the crucible process, is a melting, rather than a refining, method for making steel.

Tropenas steel castings are made by first melting the material in a cupola and then changing it to steel by means of a converter. A typical charge for the cupola would consist of about 63 per cent of pig iron, 20 per cent of steel or wrought scrap, and about 17 per cent return scrap, that is to say, sink heads and gates from steel castings.

It is to be noted that the resulting product of the cupola comes more or less under the head of what is known to the trade as semi-steel. This semi-steel is tapped from the cupola into the converter and by means of a blast of air the carbon, silicon, and manganese are burned out. Ferromanganese, ferrosilicon or silicon spiegel are then added to give the desired amounts of carbon, manganese, and silicon.

The Tropenas process is essentially the old well-known Bessemer process under a new name and on a smaller scale. Its main claim to superiority over the latter being that the air for combustion is not blown through the metal but on the surface of it. Like the Bessemer, it is also inferior to the open-hearth process.

Without the most careful selection of coke for melting in the cupola, high-phosphorus and high-sulphur steel will result. Great care must be exercised in selecting and analyzing the pig iron used, as the phosphorus and sulphur therein are not removed. The failure or success of this method of making steel castings is largely dependent upon the skill of the particular melter in charge.

Steel made by this process has the valuable characteristic of being extremely fluid owing to its high temperature. It is not, however, as well adapted to the making of small steel castings as the crucible process, because the metal must be taken from the converter and poured into the mould from ladles which are at a much lower temperature than the converter, whereas in the crucible process the steel is poured from the crucible in which it was melted.

The Tropenas process, as generally practised, overcomes the defects of the crucible process, in that the carbon is more or less under control and lower carbon steel can be made, but great and wide fluctuations may occur from day to day in the different plants in the percentages of phosphorus and sulphur.

Below are given the analyses of castings from two different plants:

Silicon.	Manganese.	Phosphorus.	Sulphur.	Carbon.
0.41	0.29	0.052	0.050	0.46
0.24	0.71	0.100	0.043	0.32

As far as a commercial proposition is concerned, and as far as the day in and day out practice of making *good* steel castings is concerned, neither the crucible nor the Tropenas process seems to exactly fill the bill. The majority of the purchasers of steel castings buy without the rigid requirement of specifications, because to meet the specifications the manufacturer generally exacts an increased price, and therefore it is this day-in and day-out practice that the average customer is interested in.

To the purchaser who requires soft or medium castings the crucible process holds out little hope, and in the Tropenas process the case is little, if any, more encouraging because of the phosphorus and sulphur.

In the former, the manufacturer hopes as to his carbon and softness of his castings, while in the latter he does the best he can with the materials on hand and trusts his castings will not be too cold short.

The quality of steel castings made by the open-hearth furnace is far superior to those made by either of the processes mentioned, but, owing to the difficulty in handling the product, it is not generally used in the making of small steel castings in this country.

Electric Furnace Castings.

The needs for and the increase in the number of electric furnaces are closely related to the introduction of the automobile and the requirements of the builders thereof.

The electric furnace, like the automobile, came in with the century. In 1904 there were only four electric furnaces in Europe, whereas there are now over one hundred.

Unlike the automobile in this particular, however, while America produces the greatest number, it is far behind Europe in the adoption of the electric furnace. Foreign automobiles are held at a premium in the United States and many manufacturers here go to Europe for materials which, they say, cannot be procured in similar quality in this country.

An examination into Europe's metallurgical methods bears evidence to the fact that many crucible steel plants have discarded and abandoned their crucible furnaces and installed electric furnaces. In the United States electric furnaces have been installed for the making of tool steel or refining steel made by the Bessemer or even the open-hearth process.

While electric furnaces require for their successful operation a chemical and physical laboratory and the best of technical knowledge, they do make good steel starting with either hot or cold raw material of any composition, pig iron, steel scrap, or even from iron ore. The secret of success is in the procuring of a high temperature, the absolute control of the percentages of the elements which go to make up good steel, and the fact that the bath of molten steel can rest a long time underneath a neutral slag, permitting the removal of any gases or included slag, and the proper co-ordination of these various factors.

Electric furnace steel can be made with any carbon content, phosphorus can be reduced when desired to between 0.01 and 0.02 per cent and sulphur can be kept within the same limits. In fact, as stated, all the elements are within absolute control, as the metal need not be tapped from the furnace until its chemical and physical character meet the wishes of the melter, and in turn correspond exactly with the specifications of the consumer.

These valuable features are found in no other known metallurgical process for iron or steel, nor are they so easily attainable, nor to such a degree, by other means as they are in the electric furnace.

Self-Cleaning Still.

In distilling apparatus for water the impurities from the water usually concentrate and accumulate in the bottom portion of the retort of the still. At regular intervals they must be removed either by hand or are drawn off through a valve-controlled opening in the bottom of the retort. In both cases the continuity of operations is impaired.

This disadvantage is overcome in an automatic self-cleaning still recently devised by Mr. W. H. McCune, chief chemist of the American Sheet and Tin Plate Co., of Vandergrift, Pa. The details given in the following article are taken from Mr. McCune's U. S. patent 1,010,508, of December 5, 1911. The essential feature is the provision of automatic means for automatically flushing the retort of the still at predetermined intervals for the removal of the collected solids. The length of the intervals in which this happens can easily be adjusted as will be seen.

Fig. 1 is a vertical cross-section of the distilling apparatus in which 2 is the copper retort with tinned inner surface

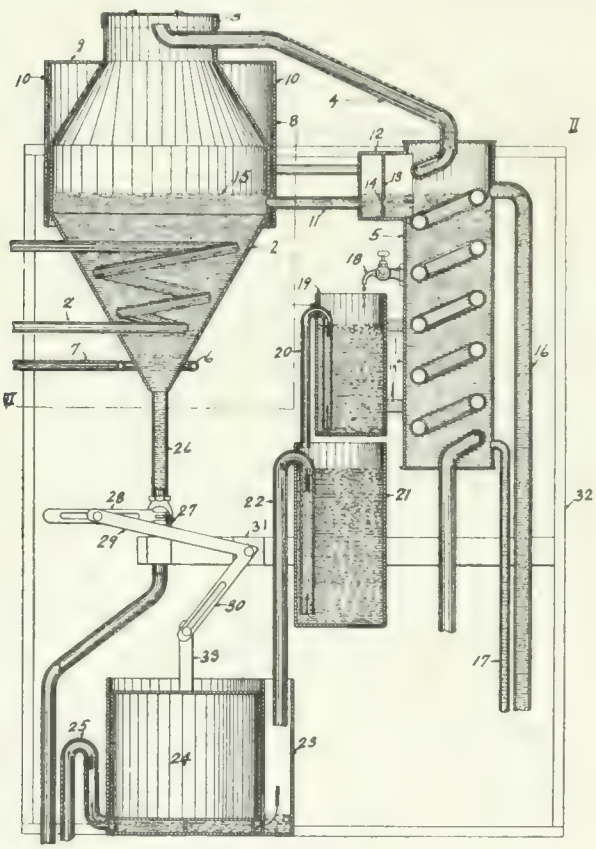

FIG. 1.—DIAGRAM OF SELF-CLEANING STILL.

with a cylindrical central portion and frustro-conical top and bottom; 3 is a tightly fitting removable cover. A tubular worm 4 of block tin leads from the upper part of the retort 2 into the cooling chamber 5, in which cold water is constantly being supplied, and the steam from the retort 2 is condensed in the worm 4, the distilled water running off into a carboy. The retort 2 is heated by steam being passed through the pipe coil 2' or by an annular gas burner 6. The products of combustion are carried off through the hood 8.

The retort 2 and the cooling chamber 5 are connected together by means of the horizontal overflow pipe 11 and box 12 which contains a vertical partition 13 with a series of small holes 14 of such size as to permit water to flow from the cooling tank 5 over the retort at about the rate at which the water is vaporized in the retort. The holes 14 are, therefore, at a level slightly below the level 15 at which the water is maintained within the retort 2.

The cooling chamber 5 is further provided with a water overflow pipe 16 at the top and a water inlet pipe 17 at the bottom.

From the stop cock 18 water is permitted to drop from the cooling chamber at a prearranged rate (about which more will be said below) into a tank 19 provided with a syphon 20.

Beneath the tank 19 is a similar tank 21 of three times the capacity of tank 19, also provided with a syphon 22.

The syphon 22 discharges into the float tank 23, which is provided with a float 24 with feet on its bottom to keep the bottom of the float out of contact with the bottom of tank 23. A U-tube 25 forming a syphon is connected to the bottom of the float tank 23 so as to practically drain this tank when the syphon 25 is started in operation.

The lower, smaller end of the conical bottom on the retort 2 is provided with a drain pipe 26 and within this drain pipe is a stop cock 27 which is normally in closed position during the operation of the apparatus. The stop cock 27 is provided

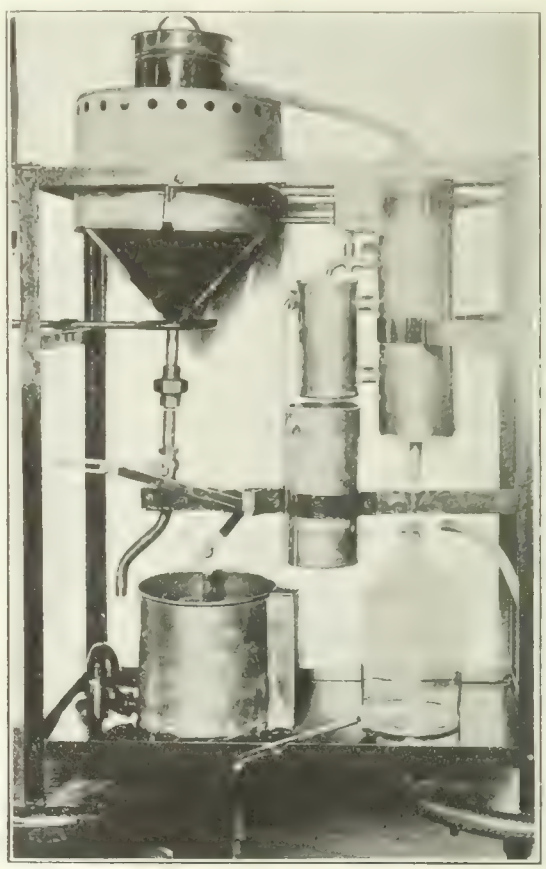

FIG. 2.—OUTSIDE VIEW OF STILL.

with an operating lever arm 28 connected to one end 29 of the bell crank formed by the levers 29 and 30. The bell crank is pivotally connected to a support 31 which is secured to the drain pipe and the framework 32 supporting the apparatus. The outer end of the lever arm 30 of the bell crank is connected to the rod 33 on the top of the float 24 so as to open and close the stop cock 27 with the rising and falling of the float in the tank 23.

So much about the construction of the apparatus. Its operation will now be easily understood. It is as follows:

Water is supplied through the pipe 17 and cooling chamber 5 to the box 12 and through this box and the pipe 11 to the retort 2, which is being heated. When the water becomes heated to the boiling point the steam passes upwardly in the retort and is led downwardly through the worm or condensing coil 4, and after the steam is condensed the resulting distilled water is led outwardly through the condensing cham-

ber 5 through the lower end of the condensing coil and is delivered into a carboy or other receptacle in readiness for use.

A supply of fresh water is constantly provided in the retort 2 through the pipe 11 and box 12 which connect the retort with the condensing chamber 25, and the condensing chamber or tank 5 is being constantly supplied with fresh water through the pipes 17, the water being constantly maintained at the desired level in the apparatus by means of the overflow pipe 16.

The stop cock 18 is opened so as to drip water slowly into the tank 19. When the tank becomes filled with water the syphon 20 operates and discharges the water in the tank 19 into the lower tank 21. Since the lower larger tank 21 has a capacity of about three times that of the upper tank 19, the tank 19 will be emptied three times before the larger tank 21 is filled sufficiently to start the syphon 22 to operate and deliver the contents of this tank 21 into the float chamber 23.

The function of the syphon will be more readily understood by first assuming a construction in which the vessel 19 and syphon 20 are absent. In such case, where water is supplied drop by drop to the vessel 21, when the water reaches the level of the top of the lower curve of the bend in the syphon 22, it will simply flow over in a thin film, no syphonic action, properly speaking, taking place. But when the contents of the tank 19 are quickly supplied to the tank 21 and the tank 21 is sufficiently full, the syphon 22 is filled to the top of its bend and a true syphonic action takes place whereby the float 24 is quickly lifted to be as quickly allowed to sink, the chamber 23 being rapidly emptied by the relatively large syphon 25.

When the water in the tank is delivered into the float tank 23, the float 24 is caused to rise in the tank 23, and through the bell crank connection formed by the rigidly connected levers 29 and 30 moves the lever 28 on the closed stop cock 27 from the horizontal position shown in Fig. 1, so as to extend vertically. When in this position the cock 27 is open and water in the bottom portion of the retort 2 will be drained from the retort. When this occurs the solid matter collected in the bottom of the retort will be carried out of the retort by the water.

When the float tank 23 has been filled with sufficient water the syphon formed by the U-pipe 25 will be started to operate and the water drained from the float tank 23.

As the level of the water in the float tank is lowered the float 24 descends in this tank and, through the connecting bell crank mechanism, closes the stop cock 27.

The frequency with which the retort 2 is drained is regulated by varying the volume of water discharged from the chamber into the syphon tank 19 by the drip cock 18 so that the number of times the retort 2 is flushed in a given time can be readily changed.

When a quantity of water has been removed from the retort 2 by flushing the retort through the drain pipe 26 the water again regains the desired level in the retort 2 in a short time (ordinarily about two minutes with the apparatus illustrated) and a continuous operation of the apparatus is practically effected.

Fig. 2 shows a still of this type which is now in regular operation. It is heated by gas alone from the outside. The efficiency of the still, however, is greater when the water is heated from the inside by means of a steam coil or by an electric heating coil.

Faraday Society.—At a meeting held in London on December 6th the following papers were presented: Dr. F. J. Brislee on the density and coefficient of lineal expansion of aluminium; Dr. V. H. Valez, on the solution volumes of nitric acid: Dr. J. N. Pring and Mr. J. R. Curzon on the influence of the physical condition of metals on cathodic overvoltage; Mr. W. R. Cooper on the Benkoe primary battery; Prof. H. Marshall on thermostats, Mr. W. R. Bousfield on thermo-regulators, and Dr. A. Cumming on thermostats, with exhibitions of these instruments by Dr. Lowry.

Metallic Roofing.*

BY JAMES A. AUPPERLE.

Experience teaches that there are ten fundamental principles which every engineer considers most carefully before drafting specifications for a roof. The ideal roof must conform to all the following requirements:

It must be (1) weatherproof, (2) fireproof. It must have (3) minimum weight and (4) maximum strength. There must be (5) provision for expansion and contraction. (6) The first cost must be low. Other requirements are (7) simplicity and low cost of application, (8) low insurance rates, (9) minimum cost of maintenance, and (10) long life and durability.

There are many excellent grades of roofing which fulfill some of these requirements perfectly, but a systematic, thorough comparison of all grades proves most conclusively that metallic roofing, as manufactured from pure iron, conforms to all the requirements and meets every condition better than any other kind of roofing manufactured to-day.

The following facts will demonstrate how uniformly the pure iron roofing meets each important requirement.

Weatherproof.

The many different styles of metallic roofing permit its application to all kinds, shapes and forms of roof construction, providing the necessary and satisfactory grade for each particular roof and the variation in pitch.

The joints are soldered, double-seamed or lapped so snugly that they are perfectly watertight.

Driven snow cannot penetrate these joints and they are impervious to capillarity which, in freezing weather, plays such havoc with slate and tile roofs.

Because of the large sections in metallic roofing there are less seams and joints exposed than in practically any other grade. There is absolutely no absorption of moisture and its destructive consequences. Therefore a metallic roof is perfectly weatherproof when properly applied.

Fireproof.

From a fireproof standpoint metallic roofing is the peer of all roofing. It is not only absolute protection against fire from without but holds and smothers the fire within, thus preventing the flames from spreading to adjacent buildings.

The lightness of this roofing obviates the danger of a heavy roof crashing through the building before the supporting timbers are half consumed.

It may be coincidental, but an investigation to learn the effect of lightning upon metallic roofing resulted in the discovery that of the many consulted there was no record of a metallic roof having been struck by lightning.

Page 702 of Foster's "Electrical Engineers' Pocketbook" contains the following statement: "A sheet of copper, a sheet of iron, a tin roof, if without breaks and fully connected by well-soldered joints, can be utilized to advantage as lightning conductors. Many architects take this into consideration, making the eaves trough and downspouting form a perfect connection to the earth."

Weight.

Comparing the weight of metallic roofing with all other roofing proves that it is as light as the very lightest forms and very much lighter than the more substantial forms of roofing such as slate, tile and concrete.

As an example, No. 20 gauge corrugated roofing, galvanized, weighs 1.78 lb. per square foot. A reinforced tile roofing weighs 13½ lb. per square foot.

This introduces one of the strongest features in favor of metallic roofing, viz., the great saving in the cost of the superstructure.

All corrugated roofing can be directly applied to the purlins.

*A paper read before the Engineers' Society of Western Pennsylvania.

V crimp, pressed standing seam and roll roofing require a very light sheathing, while in all cases a very light and less costly superstructure is perfectly adequate.

Strength.

In this respect metallic roofing again excels, presenting the very strongest form of roofing obtainable. This feature is of the utmost importance when wind pressure, snowloads and walking upon a roof are taken into consideration.

In practically all forms of metallic roofing the seams and joints are interlapped over the entire surface and the straps and cleats are in no wise exposed.

This construction has two important advantages. Firstly, the fastenings are not subjected to deterioration, and no part of the roof is dependent upon one, or a few, fastenings which may give way and cause breakage and leaks as in tile and slate, but all the fastenings act as a unit in keeping it in place. Secondly, it is absolutely impossible for the wind to get under it.

Very few roofs are constructed over which it is not necessary for someone to walk at one time or another, and no roof offers better resistance to this kind of abuse than does the metallic roof.

Corrugated roofing, because of the known tensile strength of iron, and the strength imparted by the corrugations, is not only self-supporting but is undoubtedly the very best form of roofing for large structures, mills and factories of all kinds. It is the strongest roof made.

Expansion and Contraction.

The extremes of heat and cold are amply provided for in metallic roofing. The corrugations, seams and joints are all constructed to meet this particular requirement. It is, therefore, impossible for it to crack or pull apart, but, on the other hand, it gives and returns without injury to the efficiency of the roof or tearing away from the fastenings.

First Cost and Insurance.

According to the demands and requirements of the trade metal roofing gives as low, if not a lower, first cost due to the low price of the material itself. The ease and simplicity of application emphasize this feature and it possesses the minimum possibility of poor workmanship.

The highest tribute to metallic roofing is presented by the insurance writers. In this respect it represents a great saving because it receives the lowest rates. The fact that the National Fire Protective Association places metal roofing first proves its great superiority from a fireproof standpoint.

Cost and Maintenance.

The first cost can only be correctly computed by anticipating the cost of maintenance. Those roofs which often appear cheapest are, in the long run, most costly. Because of the features found in metallic roofing, previously mentioned in this paper, the upkeep of this form of roofing compares most favorably with every other form. As has been stated, leaks can be easily found, permanently repaired, and at a minimum expense. It is waterproof, vermin-proof and does not become watersoaked, thus preventing an increased load on the superstructure. It will stand more abuse, greater extremes of temperature. It permits of remodeling, additions, and even fire does not destroy its utility.

Life and Durability.

The only just criticism offered against a metallic roof is its lack of durability. No defence can hide the fact that many metallic roofs made of steel have proved a dismal failure because of their rapid deterioration.

However, a careful review of the history of metallic roofing develops the fact that the roofs made fifty and sixty years ago did not possess this fault. On the contrary, many of these roofs are in service to-day and are still in good condition.

Further investigation into the quality or metal used proves that they were made from iron.

Some attempt has been made to explain this by calling attention to the coating applied, and claiming the life of a roof depends upon the coating and not upon the base metal. If this is true, why do galvanized, painted and tin roofs of to-day deteriorate so quickly, while these old iron roofs, sometimes on the same building, continue to withstand the ravages of time? One might surmise that the coating of to-day is inferior, but old, experienced coaters say not.

There is just one sane conclusion to be reached, and it is this, that the durability and long life of metallic roofing depend essentially upon its being made of a base metal free from those ingredients which accelerate corrosion. The electrolytic theory of corrosion is generally accepted and the impurities which hasten decay must be eliminated if long life and durability are to be attained. Having obtained the best possible base metal it is necessary that it be coated with the best protective coating obtainable.

The question has been asked, "If the base metal is so good, why coat it at all?" But the same question might be applied to other material by asking "Why coat a cedar fence-post, when placing it in the ground?" The answer is obvious. But if you paint a poplar post it would hardly follow that this post will last as long as a cedar post receiving the same protection. Nor does it follow that coated steel, full of impurities, the natural accelerators of corrosion, will have the life of a coated pure iron, made to resist corrosion to the greatest possible degree.

Old-fashioned pure iron roofs were uniformly reliable. This fact has brought forth a modern pure iron, purer than the old-fashioned iron, and, although it has been in service only approximately five years, the intense and universal satisfaction it is giving in places where steel failed under the same conditions is quickly overcoming the one criticism of metallic roofing and eliminating entirely the only unsatisfactory feature.

American ingot iron[1] can be made in larger units and consequently at a lower cost than the well-made old-fashioned iron, and because of this fact it is within the means of all at a price very little higher than steel.

A brief summary why this iron possesses the required durability is as follows:

The chain from the Newburyport Bridge across the Merrimac River when examined under the microscope shows the well-known ferrite structure almost free from slag. The oxygen content is but slightly higher than ingot iron. The high purity and comparative freedom from slag and the 100 years' service of this chain prove that the purer the metal the better it will resist corrosion.

According to available records the Newburyport Bridge had not been painted for seventy years and even if it had been frequently painted we should expect the paint to wear very rapidly where the links joined, due to the expansion and contraction as well as the vibration from traffic.

The density or specfic gravity of iron has considerable influence upon the rate of corrosion; the more porous the material the more rapidly will corrosion proceed, and the deeper and more destructive will it be. As first discovered by Kalischer (A. Sang, "Corrosion of Iron and Steel," p. 43) metals conduct electricity better when their structure is crystalline. Increased conductivity implies better resistance to corrosion. American ingot iron has 50 per cent higher conductivity than average steel.

The consumer is often unable to judge which grade of material will give him the best service. There are many different grades of iron and steel on the market such as puddled iron, piled iron, ingot iron, acid and basic Bessemer, and acid and basic open hearth, and in addition the manufacture of the same kind of steel varies at different furnaces.

[1] See, for instance, this journal, vol. VIII, pp. 61 and 98.

If the consumer gives an iron of known purity a practical test and in future years desires to procure the same material he will know exactly the kind of material that has given him satisfaction.

Protective Coatings.

All iron roofing should be galvanized or painted. It has been found that ingot iron dissolves in molten spelter about one third as rapidly as steel, consequently the zinc does not become contaminated with as much dissolved iron.

That purity of spelter is of great importance from a corrosion standpoint has been proven, and we have made careful tests on the spelter coating of American ingot iron and have found that it resists the action of sal ammoniac, ammonia, dilute hydrochloric acid and caustic potash or soda better than the coating on steel. The most important point, however, is that spelter on ingot iron is from 200 per cent to 400 per cent more resistant to the action of boiling water than the spelter on steel.

In the process of manufacture of ingot iron highly oxidizing influences are required in order to eliminate the impurities which exert a marked influence upon the physical properties of iron as well as upon its rust-resisting properties. The influence of constituents usually unlooked for in ordinary chemical analysis, such as oxygen, hydrogen and nitrogen, is not fully understood. We should expect, however, that iron or steel high in oxygen will corrode rapidly due to the depolarizing effects of oxygen.

The Effect of Manganese.

Numerous investigators have studied the effect of manganese upon the corrosion of steel. Siemens (*Inst. Journal,* 1878, Vol. I., p. 44) believes that the presence of manganese in steel increases the readiness with which it corrodes. Snelus (*Inst. Journal,* 1881, Vol. I., p. 66) ascribes the pitting in steel to the irregular distribution of manganese in the metal. Turner ("The Metallurgy of Iron, p. 421) has observed that certain samples of manganese-steel rust more readily than any other variety in the collection of specimens at the University of Birmingham, while it is well known that rich ferromanganese when exposed to moist air oxidizes with extreme rapidity. Dudley (Sang, "Corrosion of Iron and Steel," p. 84) discovered some years ago that segregated manganese formed centers of corrosion and it is a generally accepted fact that steels high in manganese are peculiarly liable to oxidation.

Cushman ("Corrosion and Preservation of Iron and Steel," p. 78) has carried on some careful investigations on the effect of manganese in steel, from which we note the following: "From the standpoint of the electrolytic theory there are several reasons why the presence of manganese in steel should invite corrosion. Manganese decreases the electrical conductivity of iron, and as the percentage of manganese, starting from zero, rises the electrical resistance increases up to a certain specific maximum. It will be seen that if the presence of manganese in iron raises the electrical resistance any variation in the distribution of the manganese means that there will not be a constant electrical conductivity throughout its mass or on any given surface. There is abundant evidence to show that manganese associates itself, to a considerable extent, with sulphur when both these impurities are present in steel. That manganese sulphide shows a difference of electrical potential against iron is also well known."

These theoretical reasons, which indicate that manganese should stimulate corrosion of steel, provided it is not homogeneously distributed in the iron, appear to be justified by a number of reliable observers, among whom may be mentioned Dudley, Drown, Abel and Reynolds.

Huntley (*Journal Society of Chem. Ind.,* Vol. 28, p. 339.) deals with the corrosion of boiler steel and gives details of a case of pitting in a boiler: "Each pit was found to be the center of a blister, and the blister contained a slightly acid solution of ferrous sulphate, while the boiler water was alkaline with caustic soda. The solid matter in the envelope of the blister, which consisted of a mixture of iron oxides, acted as a semipermeable membrane, keeping apart the ferrous sulphate within and the caustic soda outside the blister. The theory advanced is that the particles of manganese sulphide segregated in the steel were oxidized by the oxygen dissolved in the boiler water to sulphuric acid and an oxide of manganese, the acid then acting locally on the surface of the boiler plate in the vicinity of the particles of sulphide of manganese. Manganese also increases the occlusion of gases in steel. It is also known to fix oxygen on certain compounds, and that even the solid salts at suitable temperatures hasten the oxidation of many substances. The metal itself will precipitate iron from its solutions and it is reasonable to infer that with iron going into solution in the presence of oxygen if there is any manganese present it will aid its precipitation as an oxide."

Stoughton (*Engineering Magazine,* July, 1911) on the corrosion of iron and steel has the following to say: "In short, manganese is only one, although perhaps one of the worst, of the evils we have to contend with. We should expect to find that the most resistant metal would be the one which was the most homogeneous in composition and because the less the amount of impurity the less the opportunity for an uneven distribution of it, we should expect that the purer the metal the more resistant it will prove to be. Both of these theories are borne out by the facts as we know them, and it has been found good practice to reduce all impurities—not only manganese, but sulphur, phosphorus, silicon, carbon and also gases which may occur with the metal, occluded in it, or separated in the form of blow-holes. It will, therefore, be readily understood that any irregularity in the composition of the metal which produces a difference in potential between two parts, no matter how close together, will increase the rate of corrosion, and this no doubt is one of the important reasons why metal charged with blow-holes or occluded gases or in which the impurities are segregated has rusted faster than better made material.

American ingot iron, especially if the manufacturers of it have succeeded in also avoiding blow-holes, oxides and slag, is a very advantageous feature and should recommend it to users on theoretical grounds at least."

Influence of Copper.

The addition of copper to ordinary steel has the property of retarding the solution of the steel in sulphuric acid. Copper is insoluble in dilute sulphuric acid and exerts a restraining influence upon the solubility in sulphuric acid of either iron or steel.

Comparisons have been made between copper and non-copper steels by Stead and Wigham (Iron and Steel Inst., 1901, Vol. 2, p. 135), who made tests on copper steel by placing samples in the Middlesborough River. While the results are somewhat confusing the steel containing the highest percentage of manganese and sulphur showed the greatest loss but this sample incidentally contained the lowest percentage of copper, while another steel, containing a trace of copper, showed less loss under the same conditions than the steel containing almost 1 per cent of copper.

Another fact very noticeable in this test is that the steel containing the lowest total impurities (excepting copper) showed the lowest loss.

Howe ("Metallurgy of Steel," p. 83) states that some Bessemer steel contains a high percentage of copper, while Campbell ("Metallurgy of Iron and Steel," p. 358) has shown that most of the Bessemer steels recorded in his book contained from 0.30 to 0.50 per cent copper.

The careful experiments conducted at Atlantic City show that Bessemer steel sheets corroded very quickly and invariably with a peculiar form of corrosion, to which Mallet (Turner, "Metallurgy of Iron," p. 418) gave the name of "tubercular corrosion," which he states is due to irregularity in the composition of the original metal, "The result is the formation of

mounds of rust, with pitting of the metal underneath. This form of corrosion is not infrequently met with in tubes, boiler and ship plates and other iron work and is usually very rapid in its destructive action."

If Bessemer steel invariably contains copper, as has been noted, and if it corrodes in this rapid tubercular manner the presence of copper did not retard natural corrosion while it may have retarded acid corrosion.

I have endeavored to show the harmful effect of impurities from a corrosion standpoint and I have shown that the presence of slag is not an indication of resistance to corrosion, as the Newburyport Bridge chain, after 100 years' service, is found to be almost free from slag, and of almost the same composition as ingot iron made in open-hearth furnaces.

I have also shown the influence of copper, manganese and gases and will now compare the analyses of ingot iron and the chain from the Newburyport Bridge.

	Newburyport Chain	American Ingot Iron
Carbon	.0500	.0150
Manganese	.0050	.0100
Silicon	.0190	.0040
Sulphur	.0070	.0200
Phosphorus	.0320	.0030
Copper	.0070	.0500
Oxygen	.0580	.0270
Nitrogen	.0033	.0035
Hydrogen	.0005	.0006

Having thus shown the high purity of both metals adds more evidence to the correctness of the electrolytic theory of corrosion and shows the necessity of removing those elements from iron which differ from it electrochemically, which is being done in the manufacture of American ingot iron.

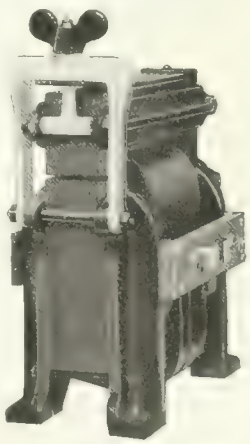
American Rolling Mill Company,
Middetown, Ohio.

Flexible Step-Up Transformers.

The use of the small high-potential transformer for commercial purposes is increasing continuously. All up-to-date electrical factories, whether they are small or large, have one or more step-up transformers for testing their products.

A high-potential transformer that is in use continuously must be constructed to stand hard usage and so designed that there is little or no chance of burning it out.

The adjoining illustration represents a type of transformer built by the Thordarson Electric Mfg. Company, 222 South Jefferson Street, Chicago, Ill., that answers all the requirements for commercial use. They are small and compact and all parts are exposed. They are designed to be run continuously, if necessary. They are constructed with a magnetic shunt and equipped with a regulating device to give instant adjustment.



STEP-UP TRANSFORMER

No impedance coil or other resistance is necessary. These transformers are designed for connection to any alternating-current circuit. They are self-regulating as far as the current consumption is concerned.

When more power or capacity is required, all that is necessary is to simply turn the thumb screw, there being no necessity to remove or loosen bolts or nuts, etc.

These transformers are finding especial favor for generating ozone, for testing insulation, for electrostatic separation, wireless telephony and telegraphy, etc.

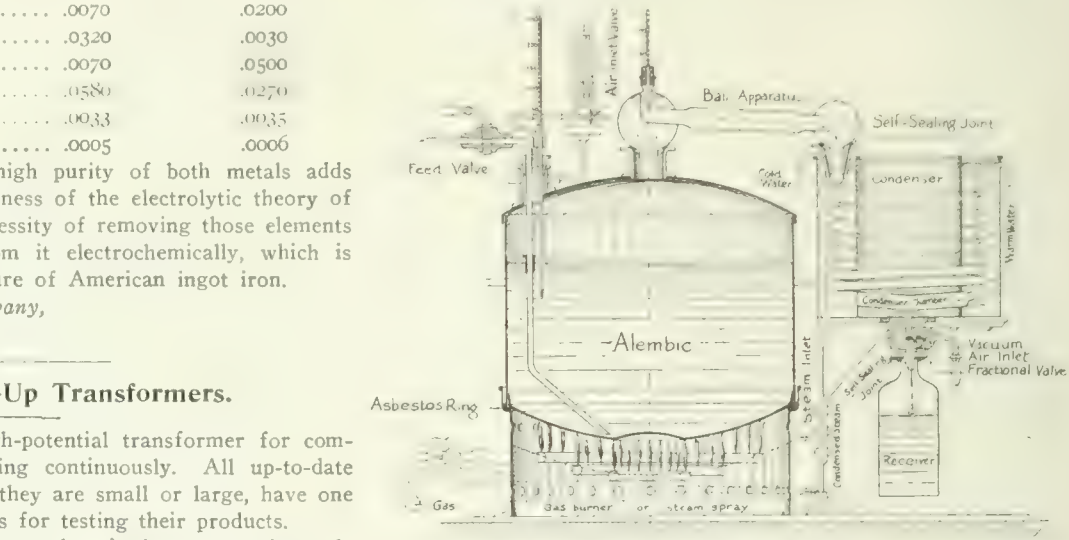
Fractional Distillation Apparatus.

There has recently been introduced in France a new type of distillation apparatus by J. Robert, for all kinds of distillation processes either under atmospheric pressure or in vacuum. It is described in the July, 1911, issue of the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale.*

The arrangement of the parts and the principles of construction and operation may be seen from inspection of the sectional drawing.

The apparatus consists essentially of the alembic, the collector and the condenser. The alembic is a vertical copper boiler with special heads and is equipped for heating either by gas or steam. The bottom head is provided with a concave depression in the center having the same diameter as the center burner; and in this way when the liquid is very low in the boiler it will be prevented from settling in the center and allowing that part of the boiler which is directly over the fire to become overheated.

The top head has two openings, one for the insertion of the inlet pipe, the thermometer and the tube leading to the pressure manometer, and the other leading to the condenser. The



FRACTIONAL DISTILLATION APPARATUS.

neck of the outlet connection is ground slightly conical and is fitted with a leather or rubber ring into which sets a glass ball which forms the collection chamber for the vapor. This form of joint automatically tightens itself as long as the pressure inside the vessel is lower than that on the outside. The vapor which collects in this ball is taken from the top by an inverted tube which is so arranged as to allow all condensate in the ball to drain back into the main vessel. The other end of the outlet tube is joined to the condenser by a similar self-sealing ball joint as may be seen in the illustration.

The condenser consists of a spiral coil immersed in running water. The pipe is large in diameter at the beginning and tapers uniformly to a smaller diameter at the opposite end where it terminates in a chamber at the bottom of the condenser.

The valve which closes the outlet of the condenser is one of the features of the apparatus. It leads directly to the vessel in which the condensate is collected. The joint between the valve and the vessel is made by a metal and a rubber ring which are tightly pressed between the lower end of the valve and the neck of the bottle by the action of the external air pressure, thus automatically sealing the joint.

Whenever it is desired to empty the contents of the vessel the valve handle is turned to the horizontal position, where the passages to the condenser and the vacuum pump are closed and air is admitted to the vessel thus allowing its removal

In replacing the vessel, it is held against the packing rings and the valve handle turned 45 deg., in which position the air inlet is closed and the vessel is connected to the vacuum pump. When the vacuum is established the valve is turned to the vertical position which places it again in communication with the condenser.

It only requires from 4 to 6 seconds to change the vessel and it is done without disturbing in the least the operation of the still.

The advantages claimed for this new type of distilling apparatus are numerous. It is simple and durable in construction and can be operated by unskilled labor. It is easily taken apart and cleaned and is especially well adapted for safe transportation. In operation it is extremely convenient. It may be operated continuously without interruption for an indefinite period. Samples of the distillate can be taken at any time and new liquid can be introduced whenever required without in any way disturbing the vacuum. These characteristics enable the apparatus to be operated without overheating and with a minimum waste of material and time. It is equally well adapted to industrial processes and laboratory analyses.

The principal dimensions and output of several of these stills are given in the following table:

DIMENSIONS AND OUTPUT OF ROBERT STILLS.

Volume of alembic in liters.	Weight of substance to be distilled, kilograms.	Output per hour, kilograms. Fractional distillation.	Output per hour, kilograms. Simple distillation.	Total height of alembic, mm.	Diameter of alembic, mm.
17	10—11	4—6	10—12	360	300
68	45—55	10—15	30—35	540	480
136	100—110	17—22	50—60	750	570

Notes.

A large crusher shaft recently repaired by the Goldschmidt thermit process indicates the application of that method to large pieces of mining and metallurgical machinery. The central shaft of a gyratory crusher belonging to the North River Stone Company, Kingston, N. Y., was 18 ft. long and varied in diameter from 12 to 22 in. At the point of fracture the shaft was 14 in. diameter. A wax mold surrounded by a sheet-metal box, packed with ground fire brick and clay, was built around the fracture, leaving a space of 2½ in. between the ends to be welded. Eleven hundred pounds of thermit, with which was mixed 25 per cent of small steel punchings, 1 per cent of chromium thermit and 1 lb. of pure carbonless manganese, was used in making the weld. After making the weld the shaft was allowed to cool for 40 hours before being inspected.

The Philadelphia Coppersmithing Co., Philadelphia, Pa., will be in their new shop, 222-224 North Front St., by Jan. 1. It is said that their new plant is one of the most modern coppersmithing shops in the country. Part of its equipment consists of seven traveling cranes. The Philadelphia Coppersmithing Company can now handle the very largest copper work. The American Evaporator Company will have offices in common with them. The apparatus sold by the American Evaporator Company will be made in this shop.

The Electro-Flex Steel Company of Dunston-on-Tyne, England, are installing an electric-steel furnace of the Stassano type.

The Reading Steel Casting Co. and the Bayonne Steel Casting Co. have been consolidated under the name of the Reading-Bayonne Steel Casting Company. The combined capacity of the two plants at Reading, Pa., and Bayonne, N. J., is from 800 tons to 1000 tons per month. They are equipped for the manufacture of medium and light-weight Trogeans steel castings.

The Florence-Goldfield mill, recently destroyed by fire, probably will be rebuilt as soon as insurance adjustment can be made. At the time of the fire the mill was running only one shift, while waiting for further mine development.

A battery of Macquisten tubes, 24 in number, has been installed at the property of the Grasselli Chemical Company, Park City, Utah, for the re-treatment of old tailings containing zinc and lead. The flotation system is expected to be successful in making a recovery where ordinary wet methods have failed.

The Richards Pulsator Classifier has been designed in a new form, known as the launder type, to meet the demand for classifiers which will furnish a classified product for one table or for any number, by simply attaching it to the launder at a suitable location near each table. The new design is expected to fill a need which the standard types do not meet.

The Colorado Grubstake and Mining Company has been organized as a permanent development of the popular Grubstake movement which originated last summer. The new company is a welcome example of the application of "safe and sane" promotion, and it remains to be seen how it will be received by the public. It has the backing of the Denver Chamber of Commerce, most of the officers of the company being officers and directors of the Chamber. Thomas Tonge, 408 Boston Bldg., Denver, Colo., is acting as secretary of the new company. The results of the prospecting which was carried on last year will be taken over by the company, as also will any promising developed or undeveloped mining properties which can be purchased on terms that would be acceptable to any of the large private exploration companies.

Personal.

Mr. Philip Argall, manager of Stratton's Independence, Ltd., has returned from London, where he went to attend the annual meeting of his company.

Mr. F. M. de Beers, general manager of the Swenson Evaporator Company, of Chicago, has gone on a business trip to Europe.

Mr. H. H. Claudet, who has until recently represented the Elmore Concentration Company in Rossland, B. C., is superintendent of the Wakefield concentrator of the Silverton mines.

Mr. Albert Ladd Colby, consulting engineer, of New York City, has returned from a three months' study of the latest developments in German By-product Coke Manufacture.

Mr. George E. Collins, of Denver, Col., has been elected president of the Colorado Scientific Society for 1912.

Dr. James Douglas has returned to New York from London. While abroad Dr. Douglas delivered an illustrated lecture on "The Development of the Copper Queen and Warren Mining District," before the Institution of Mining & Metallurgy.

Mr. D. L. H. Forbes has opened offices in Toronto, Ontario, where he will represent the Merrill Metallurgical Company as a consulting metallurgist.

Mr. Justin H. Haynes, consulting metallurgist of Denver, Col., who recently completed his work at the Hudson mill, Idaho Springs, Col., has gone to Ophir, Col., where he will be engaged for some months in experimental work at the Suffolk property.

Dr. Wilbur A. Hendryx is now in Johannesburg, South Africa, installing one of his large agitators. It is said that Dr. Hendryx has met with great success in his work in South Africa.

Mr. D. F. Sheehan has been appointed general manager of the Yampa Smelting Company, Utah, to succeed Mr. J. W. D. Moodie, resigned.

Mr. Edward S. Wiard, consulting engineer, of Denver, Colo., is on an extended tour East in the interest of clients.

Mr. Philip D. Wilson has severed his connection with the Copper Queen Mining Company, Douglas, Ariz., and has gone to Cumpas, Sonora, Mexico, for the Transvaal Copper Mining Company.

Digest of Electrochemical United States Patents Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (*Continued*).

507,130, Oct. 24, 1893, Carl Hoepfner, of Berlin, Germany. Copper and silver. Dissolves cupric chloride in a saturated solution of sodium, calcium or magnesium chloride, and uses the solution to leach ore, matte or pyrites. The copper, silver and lead are readily dissolved, especially in sulfids. If the charge contains copper oxids, an acid or other solvent is added. The dissolved silver may be first precipitated, by copper or copper sulfid, with agitation, or by electrolysis, or both the silver and copper may be simultaneously electrodeposited, the solution being passed through a cell having separate anode and cathode compartments arranged to form a zigzag path. The silver will be deposited at the first cathodes; the copper on succeeding cathodes. The electrolyte at the anodes is converted from the cuprous to the cupric form, and is afterward mixed with the solution flowing from the cathodes, to reform the leaching solution. The anodes are carbon and the cathodes copper. The diaphragms are parchment paper reinforced on one or both sides with cloth, leather, veneer, gelatine, asbestos, etc. As the solution generally contains iron, lead, arsenic, antimony, bismuth and cobalt, these may also be electrodeposited with the copper and silver, as alloys. It is preferred, however, to first precipitate them out, as by calcium carbonate. The electrolyte is also treated with calcium carbonate to remove the excess of iron. Or, air or oxygen may be injected into the electrolyte, producing oxy-chlorid of copper which percipitates the iron. The injected air, plus hydrochloric acid, may be used to convert the cuprous chlorid into the cupric form. Sulfurous acid may also be used. Caustic alkalies, alkaline-earths, carbonates, etc., may be used as precipitants for the impurities.

512,361, Jan. 9, 1894, Parker C. Choate, of New York, N. Y., Assignor to The Electrical Zinc Company, of New Jersey.

Zinc. Treats complex ores containing, besides zinc, gold, silver, iron, lead, arsenic, antimony, bismuth, cadmium, etc. The ore is first crushed and roasted at a moderate temperature to drive off any excess of sulfur. It is then mixed with coal screenings and roasted on a grate with air, at a temperature high enough to volatilize the zinc, antimony, arsenic, bismuth and cadmium; also lead. Or the charge may be subjected to a preliminary muffle roast at a temperature of from 500 to 800° F., to drive off the impurities other than lead. The iron, gold, silver, copper, nickel, etc., remain in the furnace in the form of cinder or slag, which may afterward be smelted for their recovery. The volatilized fume is caught in bags, and is electrolyzed to remove first the impurities and then the zinc. The current-density used for purifying is preferably greater than that used to deposit the zinc. Some of the impurities deposit at the cathode and others precipitate; to prevent their re-solution, the free acid liberated by the current is neutralized by the addition of more fume; or it may be drawn off as it rises to the top, neutralized in a separate tank and returned. Enough sulfuric acid should be introduced into the bath to deposit any lead. The clear solution, freed from impurities, is electrolyzed, with a carbon anode and zinc or copper cathodes, yielding commercially pure zinc.

512,362, Jan. 9, 1894, Parker C. Choate, of New York, N. Y., Assignor to The Electrical Zinc Company, of New Jersey.

Zinc. Leaches roasted ore with dilute sulfuric acid. The solution contains, besides zinc, iron, aluminium, manganese, magnesium, copper, nickel, bismuth, cadmium. The insoluble constituents, lead, gangue, etc., are settled out, and the solution is drawn off and heated to evaporate the water and crystallize the contained salts, which are recovered mostly in the form of hydrated sulfates. These are charged into a muffle furnace and heated in an oxidizing atmosphere at from 500 to 900° F., with agitation, thereby eliminating water and constituents more volatile than zinc, and decomposing sulfates other than zinc. The residual anhydrous zinc hydrate, containing also iron, copper and nickel oxids, is removed and treated with water. The zinc sulfate dissolves and is electrolyzed. The sediment is smelted.

No. 513,324, Jan. 23, 1894, H. Hirsching, assignor of one-half to Thomas R. Ellerbeck.

Precious metals. Precipitates the metals in sodium or calcium hyposulfite solutions as sulfids, by electrolysis. The cell is a vessel of wood saturated with paraffin, with suspended plate electrodes of carbon or metal. These electrodes act as agitators, being carried by a revolving frame. Contact is made by circular rings having grooves filled with mercury, into which dip the fixed terminals. The solution is preferably heated to 140° F. The complete precipitation is ascertained by use of hydrogen sulfide solution. The residual solution is again used for leaching ore, a small amount of hyposulfite being added. The precipitated sulfids are easily reduced. Impure silver may be refined by treating it with nitric acid and sodium chlorid to form silver chlorid, and mixing the latter with the sodium hyposulfite solution.

No. 518,543, April 17, 1894, H. F. Edwards, assignor of five-sixths to C. H. Hand, A. W. Hand, J. G. Merrill, G. H. Smith and S. Merrill.

Gold and silver. An electrolytic amalgamator, consisting of a vessel of wood having in the bottom a cathode layer of quicksilver, or amalgamated plates. The anodes are carbon plates secured to the sides of the vessel. Crushed ore mixed with a solution of potassium cyanide is charged into the vessel and is agitated by a revolving stirrer during the treatment. Some of the gold and silver dissolves and is re-precipitated. The free particles of gold and silver drop into the mercury.

BOOK REVIEWS.

The Principles of Electric Ware Telegraphy and Telephony. By J. A. Fleming. 906 pages, 432 illustrations. Price $7.50. New York: Longmans, Green & Co.

The subject matter of this volume represents an elaboration of lectures on radiotelegraphy delivered by Professor Fleming before various British societies and universities during the past ten years. In this, the second edition of the book, which was first published in 1906, much has been inserted on radiotelephony and the treatment of radiotelegraphy has been revised.

The author has covered in an instructive manner the phenomena involved in wireless communication, and has described in sufficient detail the various types of devices that have proved successful for this purpose. After discussing the production of high-frequency currents and electric oscillations, high-frequency electrical measurements, damping and resonance, the author deals with stationary electric waves on wires and electro-magnetic waves and describes numerous equipments for the detection and measurement of electric waves. Chapters are devoted to the evolution of electric wave telegraphy, the appliances of electric wave telegraphy, radiotelegraphic stations and radiotelephony.

No attempt has been made to avoid mathematics; in fact, mathematical treatments have been freely employed. However, in each case the treatment is as simple as the relations involved will permit to be used.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine

Vol. X — New York, February, 1912. — No. 2

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

J. W. Richards, Ph.D., President.

Salida.

To the average Eastern traveler Salida is familiar as one of the most beautiful and charming little towns in Colorado where he has to stop if he wants to take the next morning's train over the Marshall Pass to Salt Lake and where he may ascend Tenderfoot Hill right across the station in the vain hope to be considered no longer a tenderfoot. To the metallurgist the Salida smelter of the Ohio & Colorado Smelting & Refining Company conveys the idea of efficient and progressive management. The article published elsewhere in this issue on sinter-roasting with Dwight-Lloyd machines at Salida should prove particularly interesting, as it is, we believe, the first authentic description of this pioneer plant using the Dwight-Lloyd system. But this note cannot be closed without mentioning the name of F. D. Weeks, who did this pioneer work when he was smelter superintendent at Salida. Nor was it by any means his first big pioneer work; other smelters tell similar stories of him. Now more than ever men of his type are needed who, on the basis of scientific training and wide practical experience, have the courage to form a metallurgical conviction and have the greater courage and the engineering ability to transform their idea into a reality.

The Perkin Medal.

In this issue will be found a full report of the presentation of the sixth impression of the Perkin medal to Mr. Herman Frasch at the meeting of the Society of Chemical Industry on Jan. 19, in New York. The evening was as pleasant, instructive, and inspiring as any of the former presentations which have become such a charming annual feature in chemical life in New York City. The Perkin medal is now an institution—a live institution in the full sense of the word—and a brief sketch of its beginnings and history and a word on its future prospects may not be amiss on this occasion.

The fiftieth anniversary of the epoch-making discovery by William Henry Perkin of the dye-stuff "mauve," by which the foundation was laid for the now immense coal-tar industry, was fitly celebrated in 1906. Sir William Perkin came himself in the autumn of that year from England to New York to take part in the celebration which turned out a splendid success and proved especially the existence of a strong esprit de corps holding together chemical scientists, engineers, and manufacturers. It was but natural to try and find some way of preserving this spirit of united American chemical democracy.

Thus the New York section of the Society of Chemical Industry decided to found the Perkin medal, which should commemorate the inventor of mauve and act as a stimulus to American chemical research and invention. The first impression of the Perkin medal was presented by Dr. Wm. H. Nichols to Sir William Perkin on the occasion of the dinner at De-

monico's on Oct. 6, 1906, which was the climax of the jubilee of the coal-tar industry on this side of the Atlantic.

Sir William Perkin died on July 14, 1907. The Perkin medal is to live. It is being awarded every year to a chemist residing in America for achievements of high value in applied chemistry. The modus of awarding the medal has been wisely chosen to represent the spirit of American chemical democracy. According to its constitution the Perkin Medal Committee is made up of representatives of the three large chemical organizations in this country—the Society of Chemical Industry, the American Chemical Society, and the American Electrochemical Society. This committee meets to consider and discuss the various names proposed by the above and other chemical organizations of this country and then makes the award. The first meeting of the committee was held on Dec. 16, 1907, and ever since the Perkin medal has been presented at the February meeting of the New York section of the Society of Chemical Industry to a distinguished American chemist as a "beautiful token of the appreciation and affection of his fellow-chemists."

In 1908 J. B. Francis Herreshoff was the recipient—"an engineer by birth and a chemist by education"—combining mechanical engineering ingenuity and chemical science, as evidenced by his work in electrolytic copper refining and in the contact process of sulphuric acid, and by the design of the roasting furnace known by his name.

In 1909 Arno Behr was selected for his valuable work in the glucose industry, thus representing the great American industry of corn products.

In 1910 Edward Goodrich Acheson was awarded the medal as the beloved representative of American electrochemical industries—"pathfinder, conductor, switchman — everything" in the foundation of the industries of carborundum, artificial graphite, siloxicon, silicon, and now with deflocculated graphite entering resolutely into the field of applied colloid chemistry.

In 1911 another distinguished electrochemist was chosen, Charles M. Hall, whose name is forever interlinked with the aluminium industry.

And now in 1912, Herman Frasch has been the recipient for his wonderful work in oil refining and sulphur mining.

What a record of the Perkin medal and what a record of achievements of American chemists without the end yet being in sight. The Perkin medal has been on trial, so to speak, for the past six years and has not been found wanting in giving ever-fresh inspiration to American chemists. The selection of a man to be honored by the award of the Perkin medal is not an easy one and the committee has grave responsibilities. That it is a joint committee of three national societies has done more than anything else to make it truly representative. There cannot be and will not be a lowering of the standard that has been set. And fortunately every year the fact manifests itself again that, for some time at least, there will be no difficulty in finding men worthy of the honor to receive the medal which bears the name of the great founder of the coal-tar industry.

As long as this is the case the Perkin medal cannot fail to give inspiration to all who have at heart the future of American chemistry—most of all to the young American chemist. Once a year, at the Perkin medal presentation night, he may leave aside school books' wisdom and may listen to a man who has put up to Nature questions on some of its secrets in his own way and has received an answer. To listen to such a man means to get into direct contact with Mother Earth.

The Analogy Between a Blast Furnace and a Modern Building on Fire.

The appalling fire which destroyed the Equitable Building in New York City on Jan. 9 marks the end of an historic structure. The general press has lamented over the passing of so much that was of interest in connection with the building, like the Lawyers' Club, the original downtown lunch club, and the classical place where the formation of the "Steel Trust" was first conceived. The fire proved conclusively that a building of brick, stone, steel, and concrete can be destroyed by fire, and many morals have been pointed out that architects and city builders should draw from the disaster. At this place the fire may be subjected to a discussion from the standpoint of a metallurgical engineer.

For it is not at all a stress on the imagination to compare the Equitable Building on fire with a blast furnace. Like a blast furnace, the entire structure had a refractory casing. Like a blast furnace, it contained a lot of combustible material, for the woodwork, books and papers had a high calorific value. While there was no forced blast, yet the West wind delivered a large volume of air through the windows and doors, which can be regarded as the tuyeres. This blast was reinforced by the suction of the burning gases. Finally, the whole structure was effectively water-cooled by the spray and streams of scores of fire engines, and the opinion has often been expressed that an iron blast furnace should be cooled by a stream of water from top to bottom.

It is, of course, a mathematical truth that as any metallurgical furnace increases in size the percentage of heat lost by radiation decreases, for the amount of generated heat increases as the cube of any linear dimension and the amount of heat given off to the surroundings by radiation and convection increases only as the squares of any linear dimensions. It follows directly that it is much easier to attain a high temperature in a big furnace than in a small furnace. The same identical reasoning applies to the Irishman's "fireproof building on fire." With a large building the heat generated by the combustion has a comparatively smaller chance to get out and consequently the temperature attained is correspondingly higher. Practical people like the firemen and underwriters do not have the exact theoretical knowledge to confirm their practical experience or the erection of "fireproof" buildings would not have been carried to such an extreme.

The fear has often been expressed that other buildings in the downtown district are dangerous and all the more because they are called fireproof. With the great number of people congested in the lower part of Manhattan Island a general conflagration suggests sickening and frightful possibilities. The place is like a rabbit-warren and should be made like a rabbit-warren completely. All the large buildings should communicate with each other on every fifth floor and should also have communicating cellar passages. There should also be steel bridges at convenient intervals and on different levels so that

people could pass from a building on one side of the street to the other side at the higher levels.

There should be an abundance of the modern chemical fire-extinguishers which use carbonated water or carbon tetrachloride. These are most efficient to prevent incipient fires. It would be still better to have an entire system of chemical automatic extinguishers—something like the sprinkler system, but making use of the property that carbon dioxide has to prevent combustion.

Modern applied science has increased the risks of life in new ways, while it has, of course, diminished the risk of life in old days. There was a time when epidemics were havoc-workers. But bacteriology and hygiene seem to preclude this at present. We no longer are afraid of Indian raids, for the rifle has caused the Indians to be peaceful. But the danger from fire in the center of a modern city is terrible, for fireproof buildings are misnamed. It is true, however, that modern science has given us means to prevent the disasters. Unless proper regard is given to the fact that it is wrong to place combustible stuff in a structure that is refractory without efficient and perfect means for confining the fire to an insignificant space, some day the world will wake up and read about an American disaster that will be as horrible as it will be historic. With the idea fixed in the mind of the nation that a disaster is possible, but that it will be impossible if proper modern scientific means of prevention are employed, the battle is half won.

Federal Aid to Mining and Metallurgy.

Considerable misapprehension seems to exist regarding the future relations of the Bureau of Mines to the metallurgical industry. In Colorado, particularly, a great deal of misdirected energy has been expended with the approval and encouragement of men who, judging from their positions, should be better informed as to the facts and possibilities. Meetings have been held at which resolutions have been adopted, which plainly show prejudice or a failure to comprehend the situation. In view of the fact that there is a prospect of federal co-operation in the metallurgical industry, it may not be amiss to consider what, in all probability, may and may not be expected.

The keynote of the agitation has been: "Give us some method of treating our low-grade and complex ores." We omit reference to "millions of tons," which is a stock phrase lightly used, and are also cognizant of the abuse of the term "complex ore." Without decrying the desirability of finding methods of ore dressing and metallurgy applicable to some of our Western ores, we must not lose sight of the fact that vast progress has been achieved privately in the last few years, and that time and money are being expended constantly by our large companies in an endeavor to adapt further improvements. Judging from the touching appeals made for government aid, one would imagine that private enterprise is dormant, and that heroic measures are immediately necessary if the industry is to be saved from ruin. A moment's thought will show the fallacy of this attitude. Private investigation has been responsible for late advances in ore treatment, and those who place their reliance in the paternal aid of the government seem to forget that, in the event of active federal co-operation, the government probably would obtain, if possible, the services of men now engaged privately and familiar with the industry.

Prolonged metallurgical experiment costs money, and no doubt it is on this score that federal aid is urged. Elaborate experimentation is not the proper field of labor for small mining companies. It is rather for them to follow the blazed trail, adopt proved methods, and keep pace with sound improvement. Private research by large companies and wealthy individuals will always have a place in metallurgical progress, but the results in a majority of cases will be private property. The Bureau of Mines could, no doubt, find a field for research and investigation of fundamental problems, the results of which would be public property, useful to the entire industry and to the nation at large.

While misapprehension has been general regarding the function of the Bureau of Mines, the greatest stumbling block seems to have been the "government ore testing plant." The impression seems to prevail that the one thing necessary for an immediate revival and extension of mining prosperity is to have the government build and equip "ore testing plants" in various parts of the West.

Here, again, a sane conception of the purpose of an ore testing plant will clarify the view of the whole matter. An ore testing plant conveys the idea of a mill building equipped with various machines and devices embodying known processes of ore treatment. We have many such plants fostered by private enterprise and run for profit. It has been possible for years to have ores tested at these plants by various known methods or combinations of processes. With this in mind, it is difficult to see how a similar plant operated by the government would prove an open sesame to widespread mining prosperity. In fact, it could not.

There are two other functions of a testing plant, or rather, of a laboratory for metallurgical research, neither of which would encroach on private enterprise. First, after a broad survey of metallurgical progress, the merits of certain propositions might be investigated, the soundness of their mechanical and chemical principles reviewed, and their applicability broadly determined. Second, original research in fundamental problems might be undertaken. There are many of these, and the scientific results obtained would be of value to inventors or others seeking to make specific application of known scientific facts and data.

Neither of the foregoing propositions requires a commercial "testing plant," and the location of the laboratory need be of no particular concern. The West sought the establishment of the Bureau of Mines, and desires to receive some benefit from it, particularly in the metallurgical industry. It must be realized, however, that the work of the Bureau is to be along broad lines, useful to the entire country. There are also needed soundness in the representations to the Bureau and good judgment in the requests for aid; for the Bureau itself must be guided in a large measure by the representations of the constituency which it is to serve. If we have but a hazy idea of our needs we can expect no definite results from those less well informed. Finally, if the West believes in the ability of the head of the Bureau, as it does, it should make a united effort to get the necessary appropriations, and leave their final disposal to the judgment of Dr. Holmes, who has shown a commendable desire to familiarize himself with the West and with the needs of the West.

American Electrochemical Society.

The annual meeting of the American Electrochemical Society will be held early in April in Boston, Mass. The exact date has not yet been fixed.

One of the features of the professional sessions will be a symposium of papers on "electric conduction," the subject to be treated from the broadest and most fundamental viewpoints. This is being arranged at present by the president, Dr. W. R. Whitney.

Further details will be given in our next issue.

The Chicago section of the American Electrochemical Society held a highly successful midwinter meeting on January 5, at the rooms of the Western Society of Engineers, the topic of the evening being "the fixation of atmospheric nitrogen." Mr. L. L. Summers dealt in an interesting manner with the general problem and Mr. E. R. Wolcott presented an able paper on the special features of the subject. An active and prolonged discussion followed. The attendance was excellent, the local members of the American Chemical Society being present as guests.

American Institute of Mining Engineers.

The annual meeting of the American Institute of Mining Engineers will be held in New York City from Feb. 19 to 21.

Important issues bearing on the future development of the Institute will be decided at this meeting. These relate to the proposed re-classification of membership, to the proposed redistribution of the dues, and to the proposed change of name of the Institute. The name is proposed to be changed to "American Institute of Mining and Metallurgy."

It is the purpose hereafter to make the annual meeting of the Institute the most important gathering, professionally and socially, of the year and great attempts are being made by the New York members to make the meeting in February a brilliant success.

At a meeting of the New York section held on January 5th, Dr. Gardner F. Williams, of Washington, D. C., delivered an illustrated lecture on the South African Diamond Fields.

Symposium of Papers on Research.

A joint meeting of the New York Section of the American Electrochemical Society, the American Chemical Society, and the Society of Chemical Industry will be held in the Chemists' Building, 50 East Forty-first Street, New York City, on Feb. 9. The meeting will be devoted to a symposium of papers and discussions on the subject of "research."

The meeting will be held under the auspices of the New York Section of the American Electrochemical Society and will be opened by an introductory address of its chairman, Mr. Elmer A. Sperry.

The following papers will be presented:

The Commercial Aspect of Research, by Dr. Charles F. Lindsay, of the Remington Arms-Union Metallic Cartridge Company.

Research in Technical Laboratories, by Dr. Arthur M. Comey, of the E. I. du Pont de Nemours Powder Company.

Independent Research Laboratories, by Mr. P. McN. Bennie, of the FitzGerald & Bennie Laboratories.

Research in the Physics and Chemistry of Modern Roentgen Ray Practice, by Dr. W. D. Coolidge.

Dr. Leo H. Baekeland, Dr. Peter Cooper Hewitt, Dr. Edward Weston, Dr. W. R. Whitney and other prominent speakers are expected to participate in the discussions.

Since there seems to exist some confusion concerning the date of the meeting, it may be repeated that the correct date is Friday, Feb. 9.

Electric Steel Furnace.

About the recent industrial development of the Stassano electric steel furnace (the technical features of which were described in detail in an article by Major E. Stassano in our Vol. VI, p. 315, August, 1908), the following information will be of interest.

The Societa Forni Elettrici Stassano went into liquidation in December, 1909, and this enabled Major Stassano to recover, as being entitled thereto, his own patents covering the electric arc furnace of his type, which patents the company had been unable to use to advantage. Since 1909 Major Stassano has been the sole owner of the patents and since then up to the present time he has made the following installations.

For the Societa Elba one 250-kw Stassano furnace is in operation at Porto Ferrario and an 800-kw Stassano furnace is to be installed in one of its works in Liguria.

For the Milan steel foundry, Fonderia Milanes d'Acciaio, one 250-kw and two 100-kw Stassano furnaces have been installed; for the J. J. Hoehn concern two 250-kw furnaces, this plant being located at Odessa; for the Electro-Flex Steel Co., Ltd., of Newcastle-on-the-Tyne, three 250-kw furnaces. A steel works is also being installed in Dunston-on-the-Tyne exclusively with Stassano furnaces.

After several years ago the Italian War Department had adopted the Stassano furnace for their Artillery Construction Shop. The Italian Navy Departemnt will shortly likewise adopt it for the Navy Yards.

Washington Meeting of the American Chemical Society.

Again the American Chemical Society has broken its own record of attendance at the meeting held in Washington from December 27 to 30, 658 members and guests registered, and probably 700 were present. Over 250 papers were presented at the meeting.

The meeting opened on Wednesday, December 27, with a joint session of the Section on Chemical Education and the Division of Physical and Inorganic Chemistry, at which the following four papers were presented:

A. A. Noyes, on the teaching of physical chemistry.

W. D. Bancroft, on physical chemistry in the introductory course.

H. C. Jones, on the introduction of physicochemical conceptions in the early stages of the teaching of general chemistry.

J. Howard Mathews, on some applications of color photography in the teaching of physical chemistry.

In the afternoon the address of vice-president Frankforter, of Section C, entitled "the resins and their chemical relations to the terpenes," was delivered before a large audience and was followed by an address by Chairman H. P. Talbot, on the subject "privileges and responsibilities of the chemical analyst." Following Dr. Talbot, Dr. A. L. Voge, of the Library of Congress, read a paper on "Ostwald's proposed International Institute of Chemistry."

Throughout the week the Society's Divisions of Agricultural and Food Chemistry, Biological Chemistry, Industrial Chemists and Chemical Engineers, Fertilizer Chemistry, Organic Chemistry, Pharmaceutical Chemistry, Physical and Inorganic Chemistry, and the Chemistry of India Rubber, held meetings in rooms especially assigned to them.

Some 500 were present at the "smoker" on Wednesday evening, which was as much enjoyed as any that preceded it.

On Thursday evening Alexander Smith, president of the Society, delivered his presidential address, entitled "an early physical chemist," and was followed by an interesting lecture by Frank B. Kenrick and H. E. Howe, consisting chiefly of illustrations by means of the lantern of the effect of tempera-

ture, pressure, concentration, surface tension, osmotic pressure, etc., on reactions in heterogeneous systems.

A feature of the divisional meetings was the Symposium on Mineral Wastes and their Conservation, held before the Division of Industrial Chemists and Chemical Engineers on Friday. The following papers were presented:

J. A. Holmes, on carbon waste.

W. H. Bassett, on zinc losses in brass manufacture and the need of special alloys for special uses.

W. R. Whitney, on new uses to reduce abuses in conservation.

ARTHUR D. LITTLE,
PRESIDENT AMERICAN CHEMICAL SOCIETY

A. V. Bleininger, on wastes in the ceramic industry.

A. D. Little, on the abuse of brand.

F. K. Cameron, on waste and conservation of potash and phosphoric acid.

F. G. Cottrell, on sulphur fumes and flue dust.

Charles L. Parsons, on miscellaneous mineral wastes.

The Division of Pharmaceutical Chemistry held a Symposium on Drug Assaying on Friday morning and on Friday afternoon a joint meeting of the Society of Biological Chemists was held with the biological chemists of the American Chemical Society.

The secretary's report showed an increase of members of over 500 for the year, the Society's membership standing on December 1, at 5603.

At the meeting of the Council on Tuesday afternoon and evening the Biological Section of the Society was authorized to form a Biochemical Division, electing its own officers, and two new Local Sections were formed; one at Detroit and one at New Haven.

Interesting reports were received from the Committee on Standard Methods of Analysis and from the Committee on Patent and Related Legislation.

It was voted to donate the library of the American Chemical Society to the New York Chemists' Club on condition that members of the Society have ready access thereto.

The question of the time of the annual meetings of the Society was vigorously discussed, many members favoring a change from the winter season to Easter week, and a committee was appointed to take this into consideration and report to the Council.

The election of the following officers for 1912 resulted as follows: A. D. Little, president; C. L. Parsons, secretary; A. P. Hallock, treasurer. The new president, Mr. Arthur D. Little, is the well-known and distinguished chemical engineer and expert of Boston.

New Chemical Course at College of the City of New York.

The Board of Trustees of the College of the City of New York has authorized the opening of courses in the Department of Chemistry (Prof. Chas. Baskerville, Director) to mature and properly qualified applicants who may desire work in chemistry, without pursuing the full curriculum leading to a degree. Special courses are offered in analytical, industrial, organic, physical chemistry and electrochemistry, with opportunities for investigation.

The Western Metallurgical Field.

Inspiration Consolidated Copper Company.

The consolidation of the Live Oak and Inspiration copper properties which was announced in our last issue has taken definite form in the organization of the Inspiration Consolidated Copper Company, capitalized at $30,000,000 in 1,500,000 shares of $20 each. The terms of stock exchange have been announced to old stockholders in the Live Oak and Inspiration companies. Live Oak stockholders may exchange one share of old stock for two in the new company, or can receive $40 per share for their Live Oak stock. Inspiration stockholders have the alternative of selling their stock for $10 per share, or of exchanging two shares of old stock for one of new. This offer was to expire on the 29th of January. Up to the same date stockholders were to be given the opportunity of purchasing 6 per cent 10-year bonds, convertible into stock at $25. The bond issue is in the amount of $6,000,000.

The total amount of ore now developed in both properties is placed at 45,300,000 tons of 2 per cent copper content, or a total of 1,812,000,000 lb. of copper. The recovery of metal from this ore, based on 80 per cent extraction, will amount to 1,449,600,000 lb. Based on the estimates obtained from operations of other copper companies working disseminated deposits, it is thought that the cost of copper production will be about 9 cents per pound. A mill of 7500 tons daily capacity is tentatively planned, and it is thought that the new company will add from 65,000,000 to 70,000,000 lb. of copper to the annual output of the United States.

Tonopah in 1911.

The Tonopah district, Nevada, attracted considerable attention last year owing to the extensive mining and milling operations that were under way and planned. The district had five mills in operation, using modifications of amalgamation, concentration and cyanidation processes. Stamps and tube mills are used as grinders, while in cyanidation some of the latest and best practice has been developed there. The following tables are compiled from data given by the Tonopah *Miner*, and show at a glance the magnitude of operations.

Production and Values.

Company.	Tons.	Gross Value.
Tonopah Mining	173,600	$3,572,000
Tonopah Belmont	114,500	3,091,500
Montana Tonopah	52,500	761,250
Tonopah Extension	51,000	663,000

Mason Valley Smelter.

On the sixth of January the new smelter of the Mason Valley company, at Thompson, Nevada, was blown in. Con-

struction of this plant began in November, 1910, and cost about $1,000,000. During the period of smelter construction the mines owned by the company and by the Nevada Douglas Copper Company, were developed so as to provide a continuous supply of ore. On December 2 last, the first load of ore was sent to the smelter, and on the 10th of January, it was reported that ore was then being received at the rate of 700 tons per day.

The threatened litigation over smoke damage with which the company was confronted, has not amounted to anything, and it is expected that, except for the trouble caused, it will not seriously affect operations. The location of the smelter and the direction of the prevailing winds are both favorable to a rapid diffusion of smelter fumes over a country that is not occupied by agriculturists. Furthermore, the laws of Nevada are partial to the operation of the mining and smelting industries, as it was demonstrated years ago that the greatest source of wealth in the state lay in the mines. Hence, every effort has been made to encourage mining and allied industries.

Zinc in Montana.

Those conversant with conditions in Butte, predict for that district a remarkable future in the production of zinc. When W. A. Clark disposed of his copper mines to the Amalgamated interests he retained his zinc properties, and these bid fair to rival the copper mines in size of ore bodies and production of metal. The Butte & Superior company also developed immense bodies of zinc ore in the Black Rock claim adjoining Mr. Clark's Elm Orlu claim.

Several months ago Mr. Clark's concentrating works at Butte burned, and at that time zinc production from the Elm Orlu ceased. The Butte & Superior has operated for some time the old Basin Reduction Works, at Basin, Mont., but a new plant is now under construction which will employ the ordinary methods of wet concentration and, in addition, a system of flotation. Owing to certain commercial transactions with regard to a claim for almost $160,000 against the Basin Reduction works, it has been rumored that Mr. Clark is to acquire that plant and mill his zinc ores there. But the Butte & Superior lease on the plant holds until June 30, and in the event that Mr. Clark did acquire the old plant, he could not begin operations until July 1. In spite of the persistence of the rumor, it is difficult to believe that Mr. Clark will try to use the old Basin plant instead of building a modern concentrating mill. The Basin mill is ill-adapted to the concentration of zinc ores, and it is an open secret that the Butte & Superior company has sustained enormous tailing losses during its period of operation. In view of the future importance of the zinc business in Montana, and the great improvement that can be made on the Basin plant, it would seem that the lead of the Butte & Superior ought to be followed and a modern plant erected by Mr. Clark.

Lead and Zinc in the Northwest.

The fact that international boundary lines have no reference to natural geographical or geological conditions gives rise to local economic complications that are not always easy to solve. An incident in point is seen in the lead and zinc deposits of British Columbia, in which citizens of the United States are interested, and the further desire of the owners to permit the free entry of Canadian lead and zinc ores into the United States. The mining men's organization of Spokane, Washington, has recently addressed itself to the task of securing reciprocal relations between Canada and this country, whereby the duty will be removed from imported lead and zinc ores. They argue that the cost of production of metal in Canada is greater than in the United States; that much American capital is invested in Canadian mines; and that the tariff regulation regarding ore is of no advantage to the United States and serves to restrict industry. The matter is being taken up by Washington's political representatives.

The Montana Smelting Company is a new corporation recently organized to take over the interests of the Pacific Coast Smelting Refining Mining Company. It is reported that the new company will erect a lead smelter at Libby, Montana, and construct a railroad from that point to the Snowshoe mine in Idaho.

Metal Production Statistics for 1911.

The preliminary estimates of metal production in the various states for 1911 have been issued by the U. S. Geological Survey, and can be obtained in full on application to the Survey.

There was a slight decrease in gold production in the United States as compared with 1910, but silver production showed an increase of over 2,000,000 fine ounces, due largely to increased operations in copper and lead mining. The following states showed decrease in gold output: Arizona, California, Colorado, Montana, Oregon, Washington, and Alaska. Increases were noted in Idaho, Nevada, New Mexico, South Dakota and Utah. The total gold production for the United States is estimated at $96,233,528; silver at 57,796,117 fine ounces. The average price of silver in 1911 was 53 cents, a decrease of one cent compared with 1910.

The 1911 output of copper exceeded that of 1910, and nearly equalled the record production of 1909. According to statistics and estimates received the output of blister copper from domestic ores was 1,091,554,000 lb. in 1911. Arizona held first place last year, but the output will hardly equal that of 1910. Montana, in second place, also will show a decrease in production, due to the policy of curtailment inaugurated by the companies in the Butte district. The other copper producing states rank as follows: Michigan (decrease), Utah (increase), Nevada (increase), California (decrease), Alaska (increase), Tennessee (increase), Colorado (decrease), Idaho (decrease), New Mexico (increase).

Considerable increase in mine production of lead and zinc was shown in 1911. Some of the older producing districts showed slight decreases, but in Colorado and Montana the production of zinc ore was much increased. Lead fell off slightly in Colorado, but increased 50 per cent in Montana. The Joplin district fell off slightly in zinc concentrates, but gained [illegible].

Among the minor metals, quicksilver was produced in larger quantities in California, but fell off in Nevada and Texas. In Arizona, Washington, Oregon and Utah there was no production. Nevada is credited with the erection of one new 25-ton furnace by the Mercury Mining Company, at Ione. The total domestic production was 21,821 flasks of 75 lb. each, which is a gain of 1220 flasks over 1910.

There was considerable activity in tin mining in the placer fields of Alaska. Ordinary placer operations gave way to dredging, and from 80 to 100 tons of concentrate was recovered by this method. Work on cassiterite-bearing lodes was encouraging.

There was sharp falling off in the production of tungsten in 1911, owing to the decrease in the market for tool steels. Only 1125 tons of 60 per cent concentrate were marketed during the year, which is about two-thirds of the amount produced in 1910. The Boulder county, Colorado fields gave the largest domestic production, amounting to 740 tons, which is only about one-half the usual production. California was second, and smaller amounts were produced in Arizona, Nevada, Idaho and Washington.

The Non-Ferrous Metal Market.

The intervention of the holiday season had its usual effect on the metal markets, and during the last week of December and the first week of January the usual retarding influence was noticed. Copper has continued to rise since our last report, and there has been a slight flurry in tin, but otherwise the markets have been without feature.

Copper.—The bulk of the business done was for foreign

interests, and the domestic purchases have been comparatively light. The publication of the December statistics had the effect of lowering prices for actual sales, although the quotations remained almost stationary. The last quotations are 14.30 to 14.50 cents for Lake, and 14.20 to 14.30 cents for electrolytic.

Lead.—The market has been unchanged for several weeks, with quotations at 4.45 cents, New York, and 4.30 to 4.35 cents, St. Louis.

Tin.—The market was demoralized early in the month, but steadied later. Premiums were demanded for immediate delivery, in some cases as high as 1.5 cents per pound. The bulk of the business is for future delivery. January tin was quoted at 42 cents at last reports.

Spelter.—The difference in price for spot and future metal has been widened, and many consumers are taking advantage of the situation to stock up with metal for future delivery, thereby avoiding the necessity of paying premiums for immediate delivery. The last quotations were 6.25 to 6.40 cents, St. Louis, and 6.40 to 6.55 cents, New York.

Other Metals.—Business in aluminium has been without feature. Quotations are unchanged at 18.5 to 19 cents. Prices for antimony have been steady and business fair. Quotations range from 7⅜ to 7¾ cents for various brands. The quicksilver market is steady with prices at $43 per flask of 75 lb., New York. San Francisco prices are 50 cents per flask lower.

The Iron and Steel Market.

January has proved a disappointing month in the iron and steel market. While little if any ground has been lost, there has been no gain. Specifications for finished steel against contracts have been only fair, and not in proportion to the large volume of contracts entered in November and December. In pig iron, prices have held their own, but there have not been the advances which might have been expected in view of the advancing tendency displayed by steel products in December.

The disappointment in January business was due largely to the fact that high hopes were entertained. The improvement in buying in November, with an improvement even in prices in December, followed after such a long period of indifferent business that a strong reaction occurred in sentiment and the trade could see nothing but continued improvement.

Now that a period of relative quietness has intervened, the November-December improvement in trade can be studied in the retrospect with clearer perception. There were two influences: first, there was recognition by all buyers that the long continued decline, practically uninterrupted by advances during almost two years, had brought prices of finished steel products to a very low level, at which it was perfectly safe to make contracts for as long a period as the mills would permit, and to specify with some freedom against those contracts for immediate delivery; second, there was a definite movement on the part of certain railroads to buy cars, this movement being held in some well-informed quarters to have been fostered by important financial interests. The car buying was heaviest in November, while contracting was heaviest late in November and early in December, while almost throughout December there was heavy specifying.

The net result was that the mills entered the new year with a very comfortable tonnage sold on contracts for the first quarter, many contracts extending through the second quarter, while there were specifications on books in the case of bars, plates and shapes, which would run the mills for six or eight weeks. The car shops started the year with orders for more than 75,000 cars on their books, which would involve practically full operation of the car shops for about three months.

Thus fortified with actual business on books, the January quietness has not affected either prices or the rate of production. Indeed, production has increased, although but slightly. In the second half of January it has been at the rate of about 80 per cent of total capacity, against 75 per cent in November and December.

Pig Iron.

Foundry pig iron has been quiet in the past month, compared with the activity in November and December, when many consumers covered the bulk of their requirements for the early portion of the new year. The largest purchases in the Pittsburgh district were those by the Standard Sanitary Manufacturing Company, which took about 3000 tons, for first quarter delivery to its Allegheny and New Brighton plants on the basis of $13, valley. The market stiffened slightly during the month, a few sales of small lots being made at $13.25, valley, although $13 could still be done on attractive orders. In basic iron the chief activity since last report has been through the purchases of the Pittsburgh Steel Company, which on the last business day of the old year bought between 10,000 and 15,000 tons for January delivery, and in January bought an equal tonnage for February delivery. This company had formerly obtained its iron on a scale contract, with monthly price adjustment. An Allegheny valley interest bought about 10,000 tons of basic, for delivery over the first half of the year, at $12.50, valley, or a shade under that figure, while 1000 tons were sold to an eastern consumer, for second quarter only, at $12.45, valley. In Bessemer iron little was done. While furnaces continued to quote $14.25, valley, a sale of 1000 tons to a foundry interest was reported at $14.10, valley, made by a broker. Southern iron was very quiet, but furnaces maintained $10, Birmingham, as a minimum, the heaviest selling for the first quarter and half of the new year having been done in November and December at an average of about $9.75, Birmingham. Several southern producers have been adhering to a minimum of $10.25 to $10.50, Birmingham. Having made heavy sales last year for this year's delivery Buffalo sellers firmed up in prices to the extent of at least 25 cents. In eastern Pennsylvania there was heavy buying during January of low phosphorus iron, at about $17 at furnace. At the close of the month the market stands quotable as follows: Southern iron, Birmingham, $10 for No. 2 foundry; No. 2X Philadelphia $14.75 to $15; No. 2 foundry, f. o. b. Chicago furnace, $14; f. o. b., valley furnaces (90 cents higher, delivered Pittsburgh) No. 2 foundry, $13 to $13.25; forge, $12.50 to $12.75; malleable, $12.75 to $13; basic, $12.35 to $13; Bessemer, $14.25.

Steel.

The unfinished steel market scored a further advance early in January, due to mills being well sold up, with specifications coming in freely, and a level was reached of $20, Pittsburgh, for billets and $21 for sheet bars, rods being $24.50 to $25. Several of the mills in the Pittsburgh district advanced forging billets to $27 or $28, Pittsburgh, although $26 could still be done. The total advance in sheet bars from the low point toward the close of November is about $2 per ton, but most of the steel now being shipped is steel which was sold at near the low point.

Finished Material.

Current prices, f. o. b. Pittsburgh unless otherwise stated, are as follows, and are firmly maintained except as to occasional shading in sheets:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Plates, tank quality, 1.15 cents; Chicago, 1.30 cents.

Shapes, 1.15 cents.

Steel bars, 1.15 cents; Chicago, 1.25 cents.

Iron bars, 1.25 cents, Pittsburgh; 1.27½ to 1.30 cents, Philadelphia; 1.15 to 1.20 cents, Chicago.

Wire nails, base, $1.55; plain wire, 1.35 cents, base.

Black sheets, 28-gage, 1.90 cents; galvanized, 2.90 cents; painted corrugated roofing, $1.35 per square, 28-gage; galvanized, $2.50. Tin plates, $3.40 for 100-lb. cokes.

CORRESPONDENCE.

Henry Le Chatelier.

To the Editor of Metallurgical & Chemical Engineering:

Sir: The passing of the active direction of the *Revue de Metallurgie* from the hands of Prof. Le Chatelier to those of Prof. Guillet is a matter of great concern to metallurgists. However great the ability of his successor is, we cannot help regretting keenly for our own sake that we shall miss something of the influence of the older man, for till now we have had them both. Nor can we read Prof. Le Chatelier's letter, in which he announces the change in his relations, without a pang. Here again is the cry of Elijah, the deep grief of the broad and generous nature at the pettiness and selfishness of so much that forces itself on his attention.

If we measure the shortcomings of the led against the virtues of the leader we shall always have cause for despondency. But the fault is in our method of measuring. It is not with the leaders that we should compare the led of to-day, but rather with the led of ancient history. Thus read, history is an inspiration and an encouragement to those with any capacity for leadership; for though it reminds them of the great differences of level in the nature of the men of any given time, though it will not let them forget that, however equal men must be before the law, they are as noon is to twilight in their character, yet it cannot fail to assure those who will read fairly that the motives and the point of view of any given stratum of men to-day are far higher and nobler than those of the corresponding stratum in the days of Homer and of Moses. Therefore, let us be of good cheer, saying with the sage "Nevertheless, it moves."

Columbia University, New York. HENRY M. HOWE.

Flow of Heat Through Contact Surfaces.

To the Editor of Metallurgical & Chemical Engineering:

Sir: There is an unfortunate typographical error in the table published on page 43 of your January issue. For the first five values at the top of the second column on that page the first two columns should have been moved over to the right under their respective column headings like the rest of the table. The column of the "relative" values following these should not be in the column for the kw per sq. ft., as might appear from the error in the values above them; these relative values are correctly placed in a separate column without any heading, as they are only relative and not absolute.

Philadelphia, Pa. CARL HERING.

Gravity and Electromotive Force.

To the Editor of Metallurgical and Chemical Engineering:

Sir: I should like to call your attention to the fact that the electromotive force developed by gravity between two reversible electrodes placed one above the other is not quite so simply calculated as indicated in the last paragraph of Mr. Hering's letter in your January issue. This electromotive force has been computed by Dr. R. C. Tolman, who derives the following expression for iodine electrodes in an iodide solution (*Proc.* Am. Acad. of Arts and Sciences, Vol. 46, p. 114, 1910).

$$10^7 E = hg \left[T_c M_s (1 - v_s d) - M_I (1 - v_I d) \right]$$

where E = the electromotive force,
F is one faraday,
h is the distance between the electrodes,
g is the acceleration due to gravity,
T_c is the Hittorf transference number of the cation,
M_s is the molecular weight of the dissolved iodide,
M_I is the atomic weight of iodine,
d is density of the solution,
v_s is the "partial" specific volume of the salt,
v_I is the "partial" specific volume of the iodine.

Of course a similar formula would hold for any reversible pair of electrodes similarly arranged.

In the article referred to the complete bibliography on this interesting subject is given.

Boston, Mass.

Chemical Card Index of Patent Office.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—In your January issue, in the editorial on the patent reform problem, etc., reference is made to our card index of chemical literature. The number of cards it contains is slightly overstated, as at the present time it contains about one and a quarter million of cards only. All that is said, however, as to the advantages to be derived from consulting it I can heartily endorse.

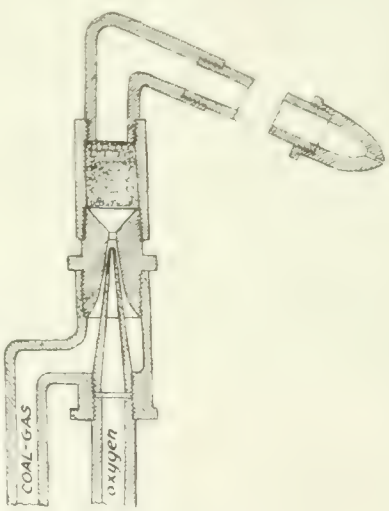
For those interested who desire to learn more about this index may I refer to two descriptive articles which have already been published in reference to it, both in the *Journal* of the American Chemical Society, viz., vol. XXII (1900), pp. 478 to 494 and vol. XXIX (1907), pp. 936 to 941? The writer is now preparing an additional article bringing the information concerning the index up to the present time. EDWIN A. HILL.

U. S. Patent Office, Washington, D. C.

The First Injector Type of Blowpipe.

To the Editor of Metallurgical & Chemical Engineering:

Sir: The general belief that Fauché constructed the first blowpipe and the injector principle is erroneous. In 1893 a patent was taken out by the Manchester Oxygen Company (Brit. Pat. No. 10,554) for an oxy-hydrogen blowpipe for which the following was claimed: "A means for the utilization of the pressure in tanks of compressed oxygen in producing the oxy-hydrogen flame, or for a blowpipe or other purposes: the employment of an injector through which the oxygen or other gas is drawn and forced forward and mixed and delivered at suitable pressures for the purpose indicated."



THE FIRST INJECTOR TYPE OF BLOWPIPE

Fauché's torch as patented ten years later differs from this blowpipe only in having a coiled or zigzag shaped tube of considerable length, designed to prevent a flashback into the acetylene pipe.

New York City. A. B. C.

Excessive Heat Insulation.

To the Editor of Metallurgical & Chemical Engineering:

Sir: It has been claimed to have been found that by increasing the thickness of the thermal insulating material of steam pipes beyond a certain amount the economy of heat begins to get worse again, and that, therefore, it is actually detrimental to go beyond a certain thickness. It has also often been stated that an insulated wire cools more rapidly when heated by a current than the same wire does when it is bare. From these it has been concluded that the same would necessarily be true with electric furnace walls.

The usual interpretation of these apparently paradoxical results is that the surface exposed to the emission of the heat to the air becomes larger. It seems to the writer that this is

not the correct one, and would lead one at times to drawing incorrect conclusions, although the increased surface of course has some effect.

The correct explanation seems to be given by the figures in the table of thermal surface-resistances published by the writer in the preceding issue of this journal, p. 43. Assuming these data to be approximately correct, it will be seen that this surface resistance for a polished copper wire to the air is far greater than that from non-metallic surfaces. Hence, when a wire is insulated the heat can get out of each square inch of surface of the insulation and into the air far easier than it can get out of the copper surface when it is bare. The intimate contact of the insulation and the copper enables the heat to pass through that interior surface without encountering a great resistance, and that surface may, therefore, be neglected. Hence, if the thermal resistance of the insulation is small as compared with this very large difference in contact resistances, then an insulated wire should cool more rapidly than the bare core does.

The same argument applies to steam pipes, and explains the alleged observed result. If such insulated pipes were covered on the outside with a sheet of polished metal, the total insulation would probably be increased, and perhaps greatly, if it is hot enough. Merely polishing the outside of the insulation, say by a sheet of glazed paper, would not, in the writer's opinion, serve this purpose, as this high surface resistance seems to require that the surface be that of a good conducting body like a metal, which brings the heat there so fast that the adhering high resisting, thin air film is formed.

It, therefore, does not seem to be correct to draw the same general conclusion for furnaces as for steam pipes or insulated wires. In the writer's opinion the safest way to get a correct understanding of the results is to consider the two kinds of insulation (solid and surface) by themselves, as was done in the table above referred to and the mate to it in the earlier issue, and then combine their effects afterwards. In one case the solid resistance may be insignificant compared with that of the surface (as in boiler pipes), and in another case the reverse may be true (as in furnaces). Two such variables acting together and each varying with the temperatures and affecting each other mutually may give all kinds of combinations, which it might be very unsafe to attempt to explain as due to one cause only, namely the thickness; the end result might, however, be given in a single equation.

For well designed furnace walls the surface resistance is surely far smaller, and therefore far less important, than the solid resistance of the wall material. Hence, the insulation in general should continue to increase with an increased thickness.

Philadelphia, Pa. CARL HERING.

Electric Shaft Furnace Design.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—Your December issue contains on page 669 a note on my American patent 996,492. To supplement the information there given I would like to call the attention of those interested in electric shaft furnace design also to Fig. 4 in my patent.

With electric furnaces of the resistance type with a vertical upper electrode and a reduction shaft it is a very essential point that the shaft terminate into the melting chamber so near to the base of the electrode that the new charge from the shaft always replaces the material sinking down round the electrode in such a manner as to enable the material to surround the electrode on all sides, so that no arcs can form round the base of the electrode. In order to have the electrode always embedded in the charge, the design of the shaft is important.

If the material is not fed from the shaft to the melting chamber in this way, the electrode will burn itself free, and the furnace will work as an arc furnace. The melting will then go on at the end of the electrode in the upper part of the melting chamber, and not at the bottom. In other words, the furnace then works as an arc furnace and not as a resistance furnace, and has not all the advantages of the latter type. This arrangement is also protected in my U. S. patent.

The patent rights of these furnaces belong to the Tinfos Papirfabrik and the writer.

A 500-kw furnace of this type has been working at Tinfos from January, 1910, and has proven successful in all respects.

At Notodden, Norway, is now in course of erection an iron works which will utilize 15,000 hp. from the Tinfos power plant. Furnaces of 5000 hp. capacity will be ready for operation in the Spring of 1912.

Notodden, Norway H. BJ. LORENZEN.

Electric Reduction of Iron Ores at Trollhättan.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—Mr. Otto Frick, in his article in your December issue (Vol. IX., page 631) makes some criticisms of my report on the electric furnace, erected by "Jernkontoret" for the reduction of iron ore (Redogörelse för Jernkontorets Försöksverk i Trollhättan). I take the liberty to rectify some of Mr. Frick's mistakes and hasty conclusions.

Mr. Frick says that the size of the shaft of the Trollhättan furnace has been calculated on the assumption that the proportion of volume of charge in 24 hours to volume of *shaft* equal 1.55. In my report you will find that the volume of charge in 24 hours to volume of *furnace* was taken as 1.55.

Mr. Frick points out that in the Trollhättan furnace the circulating gas is not heated outside of the furnace. This is quite correct. But such a process has been discussed by us for the past five years, without having been found practical. For this reason it has not been tried at the present plant.

Mr. Frick says that "the corresponding volume in the case of the Noble furnace has been only 7.9 cu. m., and this has proved to be more than ample." I cannot judge of the Noble furnace, but I do know that the volume of the shaft of the Trollhättan furnace, 25.55 cu. m., is *not* unnecessarily large under prevailing circumstances.

Mr. Frick gives the average temperature at the lower end of the shaft as 510° C. (maximum 682°, minimum 241°). Mr. Frick overlooks that these temperatures were measured at the inside of the brick lining of the shaft and not in the center. Later observations in the center have given temperatures up to 965° C. at the same level.

Mr. Frick says it should always be made a rule to burn the limestone outside of an electric furnace, because the use of burnt lime is economical for the process. This probably is correct in theory, but in practice we have found among other things, that it causes the burden to hang.

Mr. Frick says that no figures with regard to the temperature of the pig and the slag were given. However, the report includes a table, giving the results of 37 such observations of the temperature of pig as well as slag.

Much more could be said, as with the above I have only touched some of the more essential points.

Stockholm, Sweden. J. A. LEFFLER.

Electric Induction Furnace Design and Electric Steel Furnaces.

To the Editor of Metallurgical and Chemical Engineering:

Sir: In your December issue (page 625) Mr. F. A. J. FitzGerald says that his remark that "the Roechling-Rodenhauser furnace for such sizes would be found greatly superior to other forms of induction furnaces" was an expression of an opinion based on his own experience, *so far as it goes.*

At the meeting of the American Electrochemical Society at which this matter came up, only a 30-ton furnace of my system was under consideration, designed for keeping the molten charge hot and for "killing" (dead-melting) of the steel. This

30-ton furnace had been calculated on the basis of the performance of my 5-ton furnace in actual practice.

Now Mr. FitzGerald cannot draw any conclusions on the superiority of the Roechling-Rodenhauser furnace in view of the fact that Messrs. W. Rodenhauser and J. Schoenawa in their book "Elektrische Oefen in der Eisenindustrie" (Leipzig, 1911), write as follows on page 179:

"The largest unit, so far built, of a Roechling-Rodenhauser furnace has a capacity of 8 tons and gives excellent results in actual operation in the Roechling Iron and Steel Works. This capacity, however, is by no means the upper limit for the construction or commercial use of the furnace. For furnaces up to 16 tons capacity the details of design have been definitely fixed *so that for the present this size may be considered as the upper limit for which good conditions of operation may be expected with ce tainty.*"

I had an opportunity to discuss this point in May, 1909, before the Iron and Steel Institute in London. On that occasion I pointed out that the design of the Kjellin furnace makes large capacities an impossibility, due to the great distance of the bath from the primary coils and the magnet. This is a drawback of the Kjellin furnace (and, of course, also a defect incident to the Roechling-Rodenhauser furnace) and this defect increases as such in proportion with the size of the furnace. Experience also proves that the power factor decreases quickly with increasing size of the Kjellin furnace. (I take the liberty to refer here to my construction mentioned in U. S. patent 980,259, March 1, 1911, where the body of the magnet is made hollow and can, therefore, be placed close to the bath and the copper coils, even if the diameter of the bath is increased to any desired degree.)

Mr. FitzGerald is certainly not aware of the fact that the designer of the Roechling-Rodenhauser furnace himself limits the capacity of his furnace as quoted above.

Further, when Mr. FitzGerald quotes a statement of Prof. Richards that I also use an electrode furnace for working up scrap, I beg to say that this information is wrong. I presume the statement referred to *one* of my induction-furnace patents. This patent covers a construction very much like the Roechling-Rodenhauser furnace, and refers to the use of auxiliary electrodes to which electrical energy is supplied from special coils around the magnet for additional heating of the slag-layer.

With respect to the latter point I refer to the two German patents 199,354 and 216,734 and especially to the first and third claims in the latter patent, the priority of which dates from May 5, 1906, while the patent first mentioned (Roechling's) is dated May 6, 1906. The difference between the two types of auxiliary secondary circuits is that Roechling passes his auxiliary secondary currents through the lining of the furnace and the molten steel, while I pass the auxiliary secondary currents through the slag layer for the purpose of heating it in this manner.

While mentioning this, I like to reply through your journal to a remark in Mr. Rodenhauser's "Electrische Oefen in der Eisenindustrie." On page 199 he says: "Hiorth has probably recognized in the mean time that this furnace construction is worthless."

This is not at all the case.

At the same time I wish to call attention to the way in which Messrs. Rodenhauser and Schoenawa describe my latest pure induction furnace in their book, where it is illustrated in Fig. 121 on page 200. In this illustration there is only shown a side-elevation of my furnace whereby in a high degree it resembles Kjellin's and other similar constructions, while not even an allusion is made to any drawing showing the principal features of my furnace, viz., *coiling of both legs of the magnet*, which was patented by me a long time before the Roechling-Rodenhauser furnaces were constructed.

In addition I may mention that in my furnace I need no blowing arrangement, the magnet as well as the upper coil being self-cooling and not [illegible] and that [illegible] tion the bath may be tilted independently of the magnet.

In view of all these facts and the further one that the construction, on account of its great simplicity and other advantages, is much cheaper than that of the Roechling-Rodenhauser furnace, I must admit that I am unable to understand Mr. FitzGerald's remark that the Roechling-Rodenhauser furnaces are superior in all respects to all other forms of induction furnaces.

On the contrary, I cannot see myself *any* advantage in the Roechling-Rodenhauser furnace in comparison with my furnaces, especially not for the large capacities here under consideration.

[illegible]

* * *

To the Editor of Metallurgical and Chemical Engineering:

Sir: It is not necessary that Mr. Hiorth should understand my remark "that the Röchling-Rodenhauser furnaces in all respects are superior to all other forms of induction furnaces" because I did not make such a remark. The notion I tried to convey was that so far as my experience went the Röchling-Rodenhauser was superior to other induction furnaces. No one would be better pleased than I, were Mr. Hiorth to construct a 30-ton furnace which was vastly superior to any other steel furnaces in existence. Several years' experience with electric furnaces, however, has convinced me of the folly of thinking any furnace that has not advanced beyond the paper stage superior to a furnace which is actually working successfully. Mr. Hiorth's letter does not produce any evidence that he has a furnace working that is superior to the Röchling-Rodenhauser apparatus.

As regards the quotation from Professor Richards' article: I had supposed this was authoritative, and it is to be regretted that Mr. Hiorth did not correct it at once when it appeared originally.

If I may take a little more of your space I would like to point out that ever since the electric steel furnace came into prominence its commercial development has been seriously hampered by the controversial methods of the numerous people engaged on various designs. This certainly has not tended to help any of the controversialists in making a money success of their various designs. A proper rivalry in such a case is a good thing, in that it stimulates the designer to try so to improve his furnace that it will have superiorities over those of his rivals. Thus, a Rodenhauser may try to make designs which will enable him to use the induction principle in large furnaces where refining can be carried on, for in that way he avoids the difficult problems of roofs and electrodes. A Héroult may improve a poly-electrode furnace so that the difficulties of the electrode are less than the objections to low power factor and high cost of construction. A Hiorth may make designs involving the induction principle which may greatly decrease construction cost and enable furnaces of much larger capacity to be used. But the rivalry which is chiefly busied in trying to show that another designer's furnace is bad: that the V furnace is a humbug and is never run except when prospective customers visit the plant; that the W furnace has a lining which comes up every time you make a heat; that the X furnace makes bad steel full of slag; that the Y furnace has absolutely no advantages over the Z furnace, is a rivalry which does no one any good, but simply makes the potential user highly suspicious of all electric furnaces. Then on top of all this we have the continual hurling of missiles in the shape of patents of more or less value, but certainly all tacked on to the original ideas of Siemens, Ferranti, and Colby.

Although I have never been in Missouri, when it comes to opinions on steel furnaces I am a psychological native of that state.

FRANCIS [illegible] FITZGERALD,

[illegible]

Presentation of the Perkin Medal to Herman Frasch

As noticed in our last issue, the Perkin Medal Committee (consisting of representatives of the Society of Chemical Industry, the American Chemical Society and the American Electrochemical Society) at its meeting of Dec. 15 awarded the Perkin medal for this year unanimously to Mr. Herman Frasch.

The formal presentation of the medal to Mr. Frasch was made at the meeting of the New York Section of the Society of Chemical Industry, held in the Chemists' Club in New York on Jan 19.

The attendance was excellent. Rumford Hall and the balcony were well filled and the occasion was graced by the presence of many ladies.

The program was exceedingly well arranged and nicely balanced with the presentation speech of Dr. Chandler and Mr. Frasch's reply at the beginning, Captain Lucas' geological address at the end and in the midst the delightful intermezzo of Mr. Pough's moving picture exhibition.

The meeting was called to order by Prof. M. C. WHITAKER, who in a few, brief, graceful introductory remarks referred to the scope and importance of the Perkin medal and introduced the beloved dean of the chemical profession in America, Dr C. F. Chandler, "who better than any other member of our profession can speak with knowledge and with admiration of the scientific achievements of our distinguished guest of this occasion, Mr. Herman Frasch." And Dr. Chandler did speak admirably.

From a painting by Hubert Vos

HERMAN FRASCH

Dr. Chandler's Presentation Speech.

Dr. Chandler began with a brief sketch of Mr. Frasch's early life:

"Herman Frasch was born in Gaildorf, in Wurtemberg, in 1852. In 1868 he took up the practice of pharmacy, came to America and was placed in charge of the laboratory of Professor Maisch at the Philadelphia College of Pharmacy. He found, however, that industrial chemistry interested him much more than pharmaceutical chemistry, and in 1874 he established a laboratory of his own. Here began the studies and investigations which resulted in some of the most important achievements ever accomplished in industrial chemistry.

"In 1876, at the age of twenty-four, he evolved a process for refining paraffin wax which was purchased by a Cleveland petroleum company affiliated with the Standard Oil Company. These companies were so well pleased with his first invention that they induced him to give up his work in Philadelphia, move to Cleveland and make the petroleum industry his specialty. He devoted himself assiduously to the refining of petroleum and made many improvements in the processes in use, for some of which he sought and obtained patents. The first was applied for Dec. 15, 1876, when he was but twenty-four years of age. It was for an improvement in apparatus and processes for the separation and treatment of oils by more completely separating the more volatile constituents from the less volatile, in order to increase the density, improve the fire test, sweeten the odor and otherwise improve the quality. This was followed by further applications for additional improvements for the same purpose. Five such patents were applied for between 1876 and 1885, all of which were granted.

"He also obtained a patent in 1884 for the manufacture of waxed paper, a material saturated with paraffin, which has found a great variety of applications. In 1885 Mr. Frasch invented an improved petroleum oil lamp.

"Our great inventor's attention was not, however, confined to petroleum. In 1882 he invented a process for manufacturing white lead directly from the galena ore. In the same year he devoted considerable attention to improving the processes and apparatus for manufacturing salt, a subject which continued to occupy his attention for several years. Five patents for his improvements in this industry were applied for in the years 1882 to 1899 and subsequently granted.

"He also studied the ammonia process for making carbonate of soda from salt, and between 1882 and 1886 applied for four patents for improvements, all of which were granted.

"In 1883 Mr. Frasch devised a very ingenious process of making elements for thermo-electric generators. In the same year he obtained two patents for the manufacture of a superior carbon for electric light carbons, and carbons for other purposes, from 'wax tailings,' or 'still wax,' by treating the same with nitric or sulphuric acid in a specially designed furnace.

DEODORIZING OIL.

"Mr. Frasch's contracts with the various oil companies expired in 1885, and he then moved to London, Ontario, where he went into business for himself, forming the Empire Oil Company. It was here that he solved the Canadian oil problem by devising a simple process by which the offensive oils of Canada and Ohio could be made so pure that they became as valuable as the Pennsylvania oil. There had never been any difficulty in treating Pennsylvania oil so as to obtain perfectly sweet gasoline, benzine, naphtha, burning oil, lubricating oil and paraffin for the simple reason that these oils were practically free from sulphur. But the Canadian and Ohio oils contained about 1 per cent of sulphur, in such offensive combinations that it was impossible to obtain from them, by the customary processes of treatment, products that could be marketed. So they were only available for fuel purposes.

"Many chemists attacked the problem of deodorizing those oils by decomposing the sulphur compounds; many processes were devised and patented, but not one of them was satisfactory until Mr. Frasch began to study the subject. On Feb. 1, 1887, he applied for his first patent for 'Refining Canadian and Similar Petroleum Oils,' and by Dec. 31, 1894, had applied for twenty patents for his inventions in con-

ments with this object, all of which were granted. The essence of his invention consisted in distilling the different products of the fractional distillation of the crude oil with metallic oxides, especially oxide of copper, by which the sulphur was completely removed by entering into combination with the copper, while the oils distilled over as odorless and sweet as those from the best Pennsylvania oil. The process was comparatively inexpensive, as Frasch devised simple processes for separating the sulphide of copper from the residuum and restoring it by roasting to its original condition, making it possible to use it over and over again on fresh lots of oil.

"It was in the works of the Empire Oil Company that Mr. Frasch solved the problem of raising the terribly offensive sulphur-containing oils of Canada and Ohio from the low grade of fuel oils to the highest grade of purest oil. He had the process in operation on a large scale when, in May, 1888, the Standard Oil Company purchased his patents after they had been thoroughly investigated and tested by their experts. The company bought the works of the Empire Oil Company at London, Ontario, and proceeded at once to construct large works for carrying out Frasch's inventions at Lima, Cleveland, Whiting, Olean, Philadelphia and Bayonne. Mr. Frasch received in payment stock of the Standard Oil Company selling at that time for 168 and paying 7 per cent. After his process had been thoroughly established in the United States for Ohio oil he sold half his stock at 820, and the company had been paying for some time 40 per cent instead of 7 per cent.

"When one considers that the capital of the Standard Oil Company was $100,000,000, the pecuniary return from the Frasch process in the increased value of the stock and the magnitude of the greatly increased dividends assumes gigantic proportions.

"In addition to the advantages to the owners of the stock of the Standard Oil Company, there were a host of others who profited to an enormous extent. Frasch's process sent up the price of crude Ohio oil from 14 cents a barrel to $1 and above, thus benefiting the farmers and oil producers of Ohio, Indiana and Illinois, and also by greatly increasing the demand for this kind of oil until the production of this field went up to 90,000 barrels per day, giving an increase in return to the land and well owners of untold millions of dollars.

"Other inventions of Mr. Frasch in connection with petroleum refining are:

"In 1890 a process for removing from the heavier burning fraction of the oil the sulphuric acid taken up during the acid treatment by the cracked products. This he accomplished by distillation with lime.

"In 1895 processes for increasing the flow of oil wells. The Pennsylvania oil wells occur in the Devonian sandstone, and in order to rejuvenate an exhausted well it had long been customary to shatter and crack the surrounding rock by exploding one or several hundred quarts of nitroglycerine at the bottom.

"In Ohio, Indiana and Illinois the wells occur at a much deeper geological horizon in the Silurian limestones. Frasch substituted sulphuric or hydrochloric acid in place of nitroglycerine for the purpose of rejuvenating the exhausted wells, one proving best in some localities, the other in other localities, as one yields insoluble calcium sulphate and the other soluble calcium chloride.

"By plugging the wells after the acid has been poured down the pressure of the carbonic acid gas forces the acid through the most minute cracks, which are thus widened so as to open communication with new cavities of supply.

"In 1900 the application of live steam to remove completely the gasoline, naphtha and benzine from the burning oil in the process of distillation in order to raise the fire test.

"In 1902 a process for treating the peculiar crude oil of Fresno County, California, so as to remove the valuable aromatic hydrocarbons which it contains: benzol, toluol, xylol, mesitylene and naphthalene.

"In 1902 a process by which it is made possible to secure a satisfactory burning oil from the peculiar crude oil of Beaumont, Jefferson County, Texas, which consists in washing out of the burning oil fraction its peculiar smoke-producing hydrocarbons, by means of wood alcohol.

"In 1899 improved processes to bring to the surface by solution the rock salt reached by boring.

"In 1894 a process for purifying solvent extracted oils, having a special reference to linseed oil, consisting in removing the solvent naphtha from the oil by low-tension steam in a partial vacuum.

"In 1895 improvements in mining gold or like metal, which consist in saturating strata containing the diffused metal with an aqueous solution of a suitable solvent, the final solution being subsequently drawn from wells or borings through the strata.

SULPHUR.

"On Oct. 23, 1890, Mr. Frasch applied for a patent for an epoch-making improvement in the sulphur industry. It had long been known that there was a large deposit of native sulphur in Calcasieu Parish, Louisiana, at a depth of 1000 ft. below the surface. But all attempts to get at the deposit and bring the sulphur to the surface had failed completely on account of the layers of quicksand above the deposit. Mr. Frasch evolved the idea of melting the sulphur in place by means of superheated water forced down a boring and forcing the melted sulphur through an inner tube. During the period beginning Oct. 23, 1890, to Feb. 6, 1905, Frasch has applied for ten patents for his inventions of apparatus and processes for accomplishing this result.

"His efforts have been entirely successful. The Union Sulphur Company was organized, he secured control of the sulphur deposit, set up the batteries of boilers, bored the wells, built the railroad to carry the sulphur to the seaboard and the docks at Sabine Pass for the ships which deliver the sulphur to the ports accessible from the various chemical works where the sulphur is used.

"There are seven batteries of boilers, each of which runs a well. A single well delivers about 450 tons of sulphur per day. In a two months' test six wells delivered 122,000 tons of sulphur, proving the capacity of the works to exceed the entire consumption of the world.

"The sulphur is pumped into bins constructed of planks about 50 ft. high, where it congeals and forms a block of from 75,000 to 150,000 tons, over 99 per cent pure sulphur. The planks are subsequently removed, the huge block is broken up by blasting and the sulphur is loaded directly into the cars by a scooping derrick which picks up two tons at a time.

"The effect of this work on the imports of sulphur into the United States is very far-reaching, as will be seen in the following figures, showing imports and exports of sulphur into and from the United States:

	Imports, tons.	Exports, tons.
1903	188,888	None
1907	20,399	35,000

"At present the Louisiana deposit supplies this country with sulphur and might supply large quantities to European countries. Fortunately the company is owned by a few broad-minded and large-hearted men, who could not be induced to bring starvation and ruin upon the two hundred and fifty thousand people dependent upon the mining of sulphur in Sicily.

"Ninety per cent of the stock of the Union Sulphur Company is owned by Herman Frasch, the estate of H. McK. Twombly, Abram H. Hewitt and Edward Cooper and Mr. L. H. Severance.

"I have presented to you very briefly the great achievements of Mr. Frasch in the field of applied chemistry; but quite fully enough to satisfy you that your committee is fully justified in placing Mr. Frasch by the side of Sir Henry

Perkin as one of our greatest industrial chemists and chemical engineers."

Turning to Mr. Frasch, Dr. Chandler concluded:

"It gives me great pleasure, as the representative of the Society of Chemical Industry and the affiliated chemical and electrochemical societies, to place in your hands, Mr. Frasch, this beautiful token of the appreciation and affection of your fellow-chemists."

Mr. Frasch's Reply.

Mr. Frasch expressed in a few happy words his thanks for the distinction conferred on him. He then presented an exceedingly interesting address on his work, which we print here in full. It contains much that will be new even to those familiar with the oil and sulphur industries:

OIL.

"Very little is known of the impurities contained in petroleum. They influence the price, however, to a remarkable degree. The best illustration of this is the case of Ohio oil.

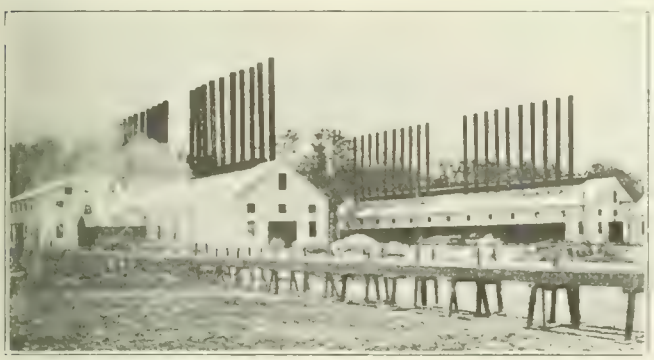


FIG. 1.—TWO OF THE SEVEN BATTERIES OF BOILERS ON THE PROPERTY OF THE UNION SULPHUR COMPANY, ONE EACH BEING USED TO PUMP A WELL.

This contains about 0.75 per cent of sulphur, and before my desulphurizing process was known sold at 14 cents per barrel, while Pennsylvania oil, with a sulphur content of only 0.03 per cent, sold at $2.25 at the same time. Sulphur affects the value of petroleum in a greater degree than phosphorus does that of iron ore.

"One of the oils which contains an objectionable amount of sulphur is that found near Petrolia, Ontario. It is the only crude that has been found in the Dominion of Canada. When this oil was first discovered in 1868 it was refined in the usual way—treated with sulphuric acid and soda and then put on the market. The result was disastrous. The odor emanating from the oil was very offensive and penetrating, so much so that the cargoes of ships carrying flour and bacon anchored near a vessel loaded with Canadian oil were spoiled, as the flour and bacon absorbed this odor. Lawsuits based upon these facts were decided against the shippers of Canadian oil and all export ceased. In order to protect the home industry, the Canadian Government imposed a duty of 9 cents per gallon on Pennsylvania oil, but in spite of this almost prohibitive duty half the oil consumed in Canada was imported from Pennsylvania.

"The offensive odor of this oil, moreover, was not its only objection. It had also the property of depositing soot upon the lamp chimney, so that a large percentage of the light emitted by the flame was lost.

"The Canadian Government, as well as the Canadian producers and refiners, made every effort to discover a method by which the objectionable properties of this crude oil could be eliminated, but practically nothing had been accomplished in twenty years, except perhaps in the matter of covering up the odor, when, in 1885, I bought a refinery in Canada and made a thorough investigation of the character of this crude and decided to discover a remedy, if possible.

"This dreadful odor, which the Canadians called 'skunk,' arose from a peculiar hydrocarbon sulphur compound, and the clouding of the lamp chimney was due to its sulphur contents. The sulphur in the oil burned into sulphuric acid, which condensed against the lamp chimney, and any unconsumed carbon or organic particles in the air would adhere thereto and form this objectionable soot. To remove the sulphur from the oil completely meant the elimination of the smoke as well as odor, and when this was effected the oil furnished an illuminant equal in quality to the best Pennsylvania.

"To free petroleum of elementary sulphur or hydrogen sulphide presents comparatively little difficulty, but the sulphur compound which is the cause of this offensive odor is very stable and cannot be broken up into hydrogen sulphide or any other sulphur compound which can be eliminated. It was because of the presence of this peculiar compound that Canadian oil for so many years resisted all the efforts made to refine it.

"This sulphur compound has the peculiarity of dissolving a number of metallic oxides. When the oil is saturated with all the oxide it can carry in solution the disagreeable odor disappears. It reappears, however, if any attempt is made to free the solution of its metal. I found that this solution of metal in petroleum has an intense affinity for sulphur, and also that, when a portion of the sulphur has been precipitated with the metal as a sulphide, additional quantities of metal oxide can go into solution. If more oxide than that necessary to precipitate all the sulphur is added to the petroleum while it is being distilled, a complete desulphurization of the petroleum is effected.

"When this petroleum solution is made with water-white petroleum distillate, which has been freed of elementary sul-

FIG. 2.—A WELL JUST STARTING TO PUMP SULPHUR.

phur and hydrogen sulphide, the solutions assume colors characteristic of each metal. The lead solution is a canary yellow, mercury orange, copper blood red, silver brown.

"I selected copper as the metal most suitable—first because it dissolves in the petroleum, and in the second place because of the readiness with which the sulphide of copper can be reconverted into oxide.

"When the laboratory work had been completed, I applied for letters patent and erected a 1200-barrel still, carrying on the process on a large scale. The shell of the still was 22 feet in diameter and 16 ft. high, and was supplied with a stirring device which kept the copper in suspension while distillation was carried on. After 80 per cent of the contents of the apparatus was distilled, the remainder, when cool, was pumped through a filter press. The solid portion was ignited and roasted, while the liquid residuum was mixed with a new charge of revivified oxide of copper to be used for the desulphurizing of a further quantity of sulphur-containing distillate. I used a shelf furnace, operated by hand, to roast the resulting sulphide of copper. In this manner I produced a burning oil containing 0.02 per cent sulphur, which is the percentage contained in Pennsylvania oil of similar specific gravity, while Canadian oil refined by the ordinary method has a sulphur content of 0.6 per cent.

OHIO OIL.

"It was about this time that oil almost identical with the Canadian was discovered in Ohio, and, while the question of refining Canadian oil was interesting, the problem became intensely important when 30,000 barrels per day were being produced in Ohio. The new field proved to be very extensive, and the Standard Oil Company bought property near Lima, Ohio, upon which they erected a large refinery. They disregarded the enormous difference in the sulphur contents of Pennsylvania and Ohio oils, decided to refine the latter in the usual way and put it on the market. When the refined product had been distributed among their customers, it all came back as unfit for use. Every effort was made to solve the difficult problem, but in 1887, after two years of experimentation and with all the skill which the Standard Oil Company could call to their assistance, it was decided that no illuminating oil could be made from Ohio crude and that it was fit only for fuel. A pipe line for this purpose was built to Chicago and long-term contracts made at 14 cents per barrel.

"My patents had now been granted and I was selling refined Canadian oil with a guarantee that it would burn equal to the best Pennsylvania. After an investigation which convinced them that I had solved this problem, the Standard Oil Company bought my patents and my refinery, and as soon as possible Lima, Cleveland, Whiting, Philadelphia and Bayonne were refining oil by the new method.

"The Ohio field was found to extend into Indiana and the production increased to 90,000 barrels per day. The price of this crude went up to nearly $1.00 per barrel, fluctuating between 60 cents and $1.00 for a great many years. The advantage resulting from the ability to use these oils for illuminants did not stop with the large profits of the Standard Oil Company, but the farmers and oil producers of Ohio and Indiana benefited by the enormous advance in the value of Ohio crude, which amounted to many millions of dollars per year.

METHODS OF DESULPHURIZATION.

"In desulphurizing petroleum, the oxide of copper is mixed with the petroleum distillate in a still supplied with an upright shaft and arms radiating therefrom, to keep the oxide in agitation during the process of distillation, flexible chains attached to the arms being used to prevent the copper from adhering to the bottom of the still. One hundred thousand pounds of oxide of copper is used for the first charge of 2000 barrels of distillate. After 80 per cent has been distilled off, a new charge of distillate is added with an additional charge of 30,000 lb. of copper, which is followed by two further runs, so that about 200,000 lb. of copper material is in the still when the fourth run is made. The residuum is pumped through a filter press, and the solid product of the filter press has the oil adhering thereto burned off. The dry mixture of oxide and sulphide of copper is then put into a roasting furnace, where it is desulphurized to 1 per cent or less.

"A variation of my method treats the vapor coming from a still charged with crude petroleum, and consists in passing the vapor through two brushes made of No. 10 steel wire, the brushes being 5½ ft. in diameter and 16 ft. long. They are inserted into a shell which is almost the same diameter as the brush, and the requisite amounts of copper and heavy oil are pumped into two shells, each containing one brush. The vapor passes, in series, first around the shell to prevent condensation; then through the shells on to the condenser. The brushes are made to revolve at about six revolutions per minute. These wires immersing continually in this oxide of copper magma, the shells containing the brushes are surrounded by the vapor coming from the still, and, as the temperatures of the vapors increase, anything condensed thereon during the prior period is re-evaporated by the hotter vapor following.

"Both these processes are now in operation at different works.

ROASTING FURNACE.

"When the question of supplying the copper necessary for the works at Lima was under discussion, it was found that 160 furnaces, such as I used in Canada, would be required to do the work. In order to avoid the handling and transportation involved in such a gigantic furnace plant, I was obliged to construct a mechanical roasting furnace of a capacity in conformity with the magnitude of the business.

"To eliminate the difficulties of the warping of the shaft and the arms which had caused the failure of the McDougal furnace, I constructed a stirring device, the shaft and arms of which were cooled artificially to withstand the high temperature of the roasting furnace. I first forced air as a cooling medium through the stirring device, but found that the oxidation of the sulphide of copper and the carbon from the residuum of the petroleum produced a temperature even higher than that of the ordinary pyrites furnace. It therefore became necessary to substitute hot water for air as a cooling medium, which proved very satisfactory. This made possible an increase in the size of the furnace to 16 ft. inside diameter, and to-day these shafts and arms are connected with stream drums and are used like a water tube boiler, so that the surplus heat extracted from the stirring device of the roasting furnace is converted into steam and utilized in the plant. The capacity of a furnace is 50 tons per day, and four to six are used in one refinery. After the copper has been revivified, it is ground and mixed with residual oil from the filter press. In this maner the copper charge is pumped into the still, which may be half a mile away. During the twenty years that this process has been in operation many millions of barrels of oil have been desulphurized.

CALIFORNIA.

"In 1902 the California field became important, and it was discovered that another oil which smoked chimneys had to be refined. This oil, however, was practically free from sulphur, the smoke being due to a large percentage of the aromatic series of hydrocarbons and to the fact that the percentage of hydrogen to carbon was too small to maintain the flame temperature necessary to consume all the carbon. I ascertained further that sulphuric anhydride converts the aromatic series into sulpho products, insoluble in petroleum, and that, by treating the distillates from the crude oil with sulphuric anhydride, the members of the aromatic series in the petroleum can readily be extracted.

"The existence of a petroleum containing nearly 50 per cent of the coal tar products is intensely interesting, especially in view of the theories advanced upon the origin of petroleum. The percentage of these hydrocarbons in the crude varies from the percentage contained in coal tar, benzol existing in a smaller proportion than toluol, while xylol represents 7 per cent of the volume of the crude. Napthaline, entirely free from all traces of carbolic odor, is quite prominent, while anthracene and carbolic acid are entirely absent.

"I employed numerous methods for separating the products of California crude by physical means. Distillation, with large back flow condensers attached, showed very encouraging results, as did also the method of washing the distillates with alcohol, carried on in series, the aromatic series being more soluble in alcohol than the paraffine series. However, the sulphuric anhydride treatment, which I first used in determining the amount of the two series contained in the petroleum, has proved to be very simple and effective on a large scale, and is now used by the Standard Oil Company at its plant in Port Richmond, Cal. The process of making the sulphuric anhydride employed there is the one purchased from the Verein Chemischer Fabriken, of Mannheim. The capacity of the plant has ben increased a number of times, until to-day it is by far the largest in the United States, if not in the world.

Sulphur

"In 1865, while boring for petroleum in Louisiana, a sulphur deposit was discovered beneath a layer of quicksand about 500 ft. thick. A result of this discovery, quarrels and con-

troversies arose as to whether the lease covering the petroleum rights also included the sulphur. It was some time before the matter was decided, and by the time a decision had been reached both parties had lost a great deal of money, and those who got the sulphur deposit lost still more in trying to exploit it. The deposit seemed to bring misfortune to every one connected with it, and I have heard many stories and met many people who told me of having lost money in the various schemes that marked the progress of the sulphur mine. Progress there seemed to mean failure. An Austrian company, a French company, and numerous American companies, everybody failed and not a ton of sulphur was produced.

"When I heard of this extraordinary situation, in 1891, I ob-

FIG. 3.—FILLING UP A BIN 50 FT. HIGH WITH SULPHUR

tained a core from the sulphur deposit and many pamphlets from the various companies who had tried to operate it, each one telling the prospective purchaser that his fortune was made if he but owned a few shares of the stock of that particular company. I became interested, and, having had a great deal of experience in drilling and mining petroleum and salt, I thought the problem might be solved if all the facts concerning the deposit were known. Unfortunately, all the drilling records had been colored by the people who expected to float companies—everything unfavorable was concealed, and only that given which would be likely to induce investment, so that what I had considered a correct report proved later to be entirely wrong.

"Being misinformed as to the character of the deposit, I reached the conclusion that the sulphur was distributed in the rock, as in Sicily, and, when I heard of the limestone roof covering the deposit, I felt that sulphur could be found anywhere within reasonable proximity to the Sulphur Mines.

"To meet the extraordinary conditions existing in this deposit, I decided that the only way to mine this sulphur was to melt it in the ground and pump it to the surface in the form of a liquid. After careful study and consideration, I became convinced that this could be done. In view of the information obtained from the various companies, I believed that there was sulphur over miles of territory, and started to drill on land I had purchased within a mile and a half of Sulphur Mine. I went down over 2000 ft. without finding anything. Then I located a second, a third and a fourth well, but found no sulphur in any instance. This took much time and money, and I finally reached the conclusion that all the sulphur was located on the land owned by the New York company operating it at the time. They had a very ingenious scheme for sinking a shaft with a shield, but after the expenditure of a great deal of money the shield was lost, and the danger due to the presence of water containing hydrogen sulphide was demonstrated by the death of a number of men. It was decided to abandon this method, especially after a drilling record had been made by a drilling company who reported direct to the owners, when it was discovered that there was no roof over the sulphur, and that sulphur water was permeating the deposit in inexhaustible quantities.

"I realized at the outset that a method entirely different from that employed in the mines of Sicily was necessary for success here, as the class of labor required to operate this mine would demand at least $5.00 per day, while the Sicilian miners were being paid 60 cents.

"I succeeded in getting possession of the property, and at once set to work to drill a well of sufficient diameter to determine finally the character of the existing material. When this had been done, I was obliged to modify completely the process and apparatus I had expected to employ.

"At that time the drilling of a well in an alluvial deposit containing quicksand, etc., was a very tedious task, and it took from six to nine months to get through the alluvial material to the rock—work which we do to-day in three days.

SULPHUR PROCESS

"I drilled a well through the alluvial deposit to the rock with a 10-in. pipe; then continued through the sulphur-deposit, which was about 200 ft. thick, with a 9-in. drill, and immersed a 6-in. pipe from the surface to the bottom in this well. The 6-in. pipe had a strainer only 6 in. long, at the very bottom and a seat to receive the 3-in. pipe through which we expected to lift the sulphur to the surface. The 6-in. pipe, directly above the seat for the 3-in. pipe, was also perforated for a distance of 3 ft.

"After the well had been drilled and before the pipes were inserted, it was filled up with sand in order to insure a tight receptacle at the bottom for the liquid sulphur. After the same

FIG. 4.—A MASS OF LOUISIANA SULPHUR READY FOR LOADING

had been washed out, the pipes were inserted and equipped, and the well was ready for the melting fluid.

"This melting fluid consisted of water super-heated to 335° Fahr. The porosity of the rock in which the melting had to be done seemed to furnish an almost insurmountable obstacle to success, as I feared that the wild waters in the rock would break into the melting zone I expected to create and reduce the temperature of the fluid with which I expected to melt below the temperature necessary to fuse the sulphur. I had supplied a large number of boilers to furnish the heat necessary to maintain in the well a temperature higher than that required for the fusion of the sulphur.

"The water was superheated in columns in which 100 lb. per square inch pressure was maintained, and the apparatus which I had constructed to accomplish this proved efficient. We used twenty 150-hp boilers for a well, which represents experimentation on a ponderous scale.

"When everything was ready to make the first trial, which would demonstrate either success or failure, we raised steam in the boilers, and sent the superheated water into the ground without a hitch. If for one instant the high temperature re-

quired should drop below the melting point of sulphur, it would mean failure, consequently intense interest centered in this first attempt.

"After permitting the melting fluid to go into the ground for twenty-four hours, I decided that sufficient material must have been melted to produce some sulphur. The pumping engine was started on the sulphur line, and the increasing strain against the engine showed that work was being done. More and more slowly went the engine, more steam was supplied, until the man at the throttle sang out at the top of his voice, 'She's pumping.' A liquid appeared in the polished rod, and when I wiped it off with my finger I found my finger covered with sulphur. Within five minutes the receptacles under pressure were opened, and a beautiful stream of the golden fluid shot into the barrels we had ready to receive the product. After pumping for about fifteen minutes, the forty barrels we had supplied were seen to be inadequate. Quickly we threw up embankments and lined them with boards to receive the sulphur that was gushing forth and since that day no further attempt has been made to provide a vessel or a mold into which to put the sulphur.

"When the sun went down we stopped the pump to hold the liquid sulphur below until we could prepare to receive more in the morning. The material on the ground had to be removed, and willing hands helped to make a clean slate for the next day. When everything had been finished, the sulphur all piled up in one heap, and the men had departed, I enjoyed all by myself this demonstration of success. I mounted the sulphur pile and seated myself on the very top. It pleased me to hear the slight noise caused by the contraction of the warm sulphur, which was like a greeting from below—proof that my object had been accomplished. Many days and many years intervened before financial success was assured, but the first step toward the ultimate goal had been achieved. We had melted the mineral in the ground and brought it to the surface as a liquid. We had demonstrated that it could be done.

"This was especially gratifying, as the criticisms I had received from technical papers and people who had heard of what I was attempting to do had been very adverse. Every one who expressed an opinion seemed to be convinced that this thing could not be done, one prominent man offering to eat every ounce of sulphur I ever pumped. A fair illustration of public opinion is the remark of the mail boy who drove me to the railroad the morning after our first pumping. He said: 'Well, you pumped sulphur sure, but nobody believed it but the old carpenter, and they say he's half crazy.'

"This severe criticism, while not agreeable, did not carry very much weight with me. I felt that I had given the subject more thought than my critics, and I went about my work as best I could, thoroughly convinced that he who laughs last laughs best.

"At first we pumped with an ordinary deep well oil pump, changed to meet the corrosive action of the sulphur. We experienced great difficulty with the valves in the pump, the high specific gravity of the sulphur, the great depth from which it had to be raised and the corrosive action of the mineral itself making the maintenance of valves very difficult. Zinc and aluminium are practically the only two metals unaffected by liquid sulphur, but both these, being soft and easily disintegrated, would not withstand the shock at the change of stroke of the pump. I decided that, if the specific gravity of the sulphur could be raised by the admixture of some other body much lighter, a point might be reached where the hydrostatic pressure of the water in the ground would raise the sulphur. Air seemed the most suitable, and we introduced compressed air into the column of liquid sulphur standing in the well, using a volume of two parts of air and one of sulphur. We have raised our sulphur discharge lines 70 ft. above the ground, so that we can fill bins to a height of 65 ft. without machinery or pump of any kind in the sulphur proper.

"The first well lasted long enough to demonstrate the possibility of success, and to indicate in what directions improve-

[illegible] Standard Oil work

[illegible] lost some wells because of the parting of the pipes. As the mineral was melted from the bottom, the earth above would follow as the sulphur rock settled. The grip of the sand and earth against the pipe was so great that, instead of sliding, it would pull the pipe in two and the well would be lost. A 12-in. pipe outside of the 10-in., with stuffing box and telescope joints, obviated this difficulty. All wells, however, are eventually broken and crushed, when the abstraction of sulphur becomes so great that the cavity made cannot withstand the weight of the ground above it.

"We succeeded in increasing the life of a well greatly by lining the hole drilled through the rock with a 9-in. perforated pipe.

"About that time we found that some wells gave out and ceased to pump when there had been no breaking of the pipes. I reached the conclusion that the cold sulphur water permeating the rock had broken into the melting zone, and brought the temperature of the melting water below the melting point of sulphur. I thought this might be remedied by pumping large amounts of a material like sawdust into the mine with the melting fluid, and that if the quantities of sawdust were large enough, the channels through which the wild waters in the rock entered the melting zone could be sealed.

"One well, after pumping about 7000 tons, at the rate of approximately 350 tons per day, ceased to produce. The pipes were all in good order, and we started to pump sawdust into the ground with the melting water. After pumping in about six carloads per day for five days, the well 'sealed' with sulphur and promptly produced 39,000 tons more before the caving of the rock broke the pipes.

"We perfected this method of artificially 'sealing' the rock surrounding a melting zone, so that the amount now obtained from a well has been greatly increased. Whenever a well breaks we shoot off with dynamite the 10-in. pipe in the quicksand above the rock, and permit the sand to follow into the cavity from which the sulphur has been abstracted, filling up the space of the extracted sulphur rock with sand. The surface, consisting of about 200 ft. of clay, follows the quicksand, gently but surely, and in order to maintain the pressure which is necessary to prevent the melting water from breaking into steam, the volume of the sulphur abstracted from below must be replaced by earth from above. To do this a dredge with a capacity of 4000 cu. yd. per day became necessary. Numerous reservoirs have been dug on the outskirts of the mine to supply the material required to do this. This filling has been going on constantly, and the ground has sunk to such an extent that where our house once stood is now 80 ft. below the original surface.

"These improvements were made slowly, as all experiments had to be made on a ponderous scale, and the smallest change required a great deal of time. During the long intervals which necessarily elapsed between my visits to the mine I could give this new enterprise no attention. It took months to drill a new well when an old one was lost. At one time the work lay idle for a whole year before I could take it up again, and it was not until 1903 that we could see financial success ahead. In that year we produced 35,000 tons, and in 1904 enough to supply the entire consumption of the United States. It was in that year that we sent the first cargo of American sulphur to France.

"In order to demonstrate what the mine could do with six wells, we pumped that number simultaneously for six months, producing 122,000 tons of sulphur, which is more than the consumption of the whole world for that period of time.

"Prior to the development of the Louisiana sulphur mine, the sulphur production of the United States was less than one-half of one per cent. of its consumption, practically the entire amount required being supplied by Sicily and Japan. The former really had a monopoly of the sulphur business for a great many years.

The Sicilian sulphur industry was closely interwoven with the Politics of the islands, both internal and external. It was in 1833 that an English fleet appeared in the Bay of Naples to compel the Italians to rescind the sulphur monopoly that had been granted to France.

"The ups and downs of the Sicilian sulphur business are extraordinary. The people, a large percentage of whom are employed in the mines, are very poor and used to be in the hands of dealers and usurers, who manipulated the sulphur market to suit themselves, and extremely high prices and extremely low prices followed each other, as suited their convenience.

"In England a process had been discovered for the recovery of sulphur from the waste products of the Leblanc soda process, quite a large amount of money being invested in the necessary machinery. When another sulphur crisis occurred in Sicily in 1894-5, and sulphur sold below the cost of production of English recovered sulphur, a number of English capitalists decided to finance and market the Sicilian output. They incorporated as the Anglo-Sicilian Sulphur Company, and succeeded in getting between 75 and 85 per cent. of the Sicilian mine owners under contract for the entire output of their mines, whatever that might be, at a fixed price. This arrangement was made with the consent of the Italian Government for a term of five years, with the privilege of renewal for five years more. The scheme proved an excellent one, both for the Anglo-Sicilian Company and for the Sicilians. The former made a great deal of money, paying about 50 per cent. per annum on their common stock, and reserved large sums for contingencies. The contingencies arose in the form of the Louisiana sulphur production, which came like a bolt out of a clear sky. They had received complaints from their agents here that the business in the West had diminished on account of sulphur furnished from a mine that was no mine at all, but where the sulphur came out of the ground ready to ship. The Anglo Company, as well as the Sicilians, declared that this was impossible, and that the whole thing was an American swindle.

FIG. 5.—MASS OF LOUISIANA SULPHUR, 48 FT. HIGH, SHOWING THE SIDE TOWARD THE TRACK WITH THE BOARDS REMOVED AND THE END WITH THE BOARDS INTACT.

"I was very anxious to get all the business possible, as our stock pile was much larger than our bank account, and I was surprised to hear that the Anglo-Sicilian Company had accepted a contract for 20,000 tons to be delivered in America, very much below the price they generally quoted, and not far above their cost. I decided to go to London and have a talk with them in order to find out if it would be necessary for us to put the price below their cost in order to maintain the American business, which we needed very badly. I was perfectly frank and explained our position fully. I met with a great lack of enthusiasm for this 'American humbug,' and was told that they would go their own way, and I could go mine. I did. I had arranged for the sale of our sulphur in the various European countries, and knowing the production cost to my competitors, I succeeded very shortly in demonstrating that Louisiana sulphur was not a swindle. I found out afterwards that the lesson had cost the Anglo-Sicilian Company 285,000 pounds sterling—but then we were friends. Their attitude changed greatly, and they decided to go out of business and let the Sicilians and Americans take care of themselves.

AN OBLIGATORY TRUST

"The Anglo-Sicilian Company, especially during the last years of its life, had found it necessary to store a great deal of the sulphur tendered to them on their contracts, as they had lost the American market, which was their best customer, and it looked very much as though this enormous accumulation, approximating 500,000 tons, would have to be thrown on the market to be sold for whatever it would bring. To the poor Sicilian miner, whose lot under the most favorable circumstances is not an enviable one, this would have meant sulphur below cost, with the eventual closing of the Sicilian mines and misery and starvation to a large population.

"The men well acquainted with the situation felt, as I did also, that this would result in revolution and bloodshed for Sicily. The laborers could not live on a wage lower than that which they already received. Frequent strikes and disturbances occurred when the misery of the working people was greater than usual.

"Understanding the peculiar character of the Sicilians, the Government, when the matter was brought to their attention, decided to form an obligatory trust, so that no sulphur would be sold below cost, and the Government was to finance the large stock on hand by issuing bonds and guaranteeing the interest. All the Sicilian sulphur mines were to be included in this obligatory trust, and the Government agreed to advance, in cash, four-fifths of the value of the sulphur when it was received from the mine owners, the remainder to be paid to them after payment for the sulphur sold had been received and the expenses of conducting the business deducted.

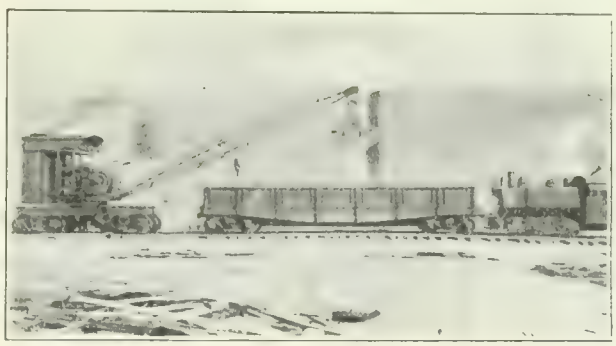

FIG. 6.—LOCOMOTIVE DERRICK LOADING A CAR WITH 25 TONS OF SULPHUR IN 14 MINUTES.

"A law creating this obligatory trust, which is known as the 'Consorzio Obbigatorio per l'Lindustria Solfifera Siciliana,' was passed, and it has been in operation since August 1, 1906. It has gone through the vicissitudes of childhood and occupies a unique position among the various trusts, which is of special interest to the United States. Here we have in successful operation a trust created by force which all those engaged in that particular business are obliged to join. It has a board of thirty directors, an executive committee of ten, four of whom are members of the government, and a Royal Commission, also appointed by the government, who is practically its president. Prices are fixed and maintained, and sulphur is sold to all comers at the same figure.

"This obligatory trust has been a godsend to the people, and so well are the Sicilians satisfied with its operation, that they have already petitioned the Government to extend the period of its life beyond that originally decided upon. Moreover, the

present Commissioner's able and wise administration has been so successful that the Sicilian stock of sulphur on hand, the obligation of the Consorzio toward the Government and the Bank of Sicily have been diminished to such an extent that the stock will be reduced to normal within two years and the Consorzio will be entirely out of debt. It is a striking illustration of the fact that a trust may be beneficial to all concerned. Great credit is due to the Italian Government for averting the misery which would inevitably have followed another sulphur crisis."

Moving Pictures.

Mr. Francis H. Pough followed with a brief but very interesting account of the works of the Union Sulphur Company, illustrated by numerous lantern slides, a few of which are reproduced in the adjoining illustrations. This was followed by an exhibition of moving pictures on the screen, giving a very vivid and direct idea of the enormous scope of the Louisiana works of the Union Sulphur Company, of the methods of working, the sanitary conditions of the workmen's houses, etc. In fact, in fifteen minutes the audience could learn practically as much as by walking over the mines for a day. Moreover, the information thus pleasantly presented was absolutely up-to-date, since the film photographs had been taken only a week ago. An exhibition of these moving pictures at some session of the coming International Congress of Applied Chemistry would certainly prove a very attractive and instructive feature.

Geology of Calcasieu Sulphur Mines and Sulphur Oil Fields of the Coastal Plain.

The concluding address of the evening was made by Captain Anthony Francis Lucas, of Washington, D. C., on the geology of the great Calcasieu sulphur mines and the sulphur oil fields of the Coastal Plain. In his impressive, instructive and interesting paper Captain Lucas proposed to touch the subject only by some practical observations, which through the success of Mr. Frasch have become of international importance, and which make me feel glad to be an American citizen.

"America stands abroad as a great country, and Americans as great men who do great things, men who, undaunted by failures of others, have undertaken and carried to practical solution problems that appeared foolhardy to undertake, and the success of this accomplishment must in all candor be ascribed to genius, especially so when this genius compels other nations to take notice and 'willy-nilly' pay him tribute.

"The geology of the coastal plain—which, of course, includes the Mounds or Domes—extends over a vast area, practically beginning at the northwestern coast of Florida for about 50 to 100 miles in width, and following the littoral zone of the Gulf States of Alabama, Mississippi, Louisiana and Texas down to Mexico and beyond.

"This vast area is practically as level as a floor, with a slight dip toward the sea, and in traveling westward one comes upon slight elevations of, say, from 10 to 100 feet in height over the surrounding prairie. These elevations, which we will later on feel warranted in calling Domes, are of limited area, say, from 250 to 2,000 acres, which have by now assumed wonderful economic importance.

"It is, therefore, precisely of these elevations that we will speak, for they now form the basis of the whole economic geology of the coastal plain in the States of Louisiana, Texas and the Gulf States of Mexico.

"To attempt to make soundings in search of minerals of economic value beyond this elevated zone is perfectly useless, as the drill will only encounter the clays, sands and gravel of the Pleistocene Columbia series, then the red sands of the Neocene Lafayette series, and deeper down the blue clays, Gumbo and sporadic laminations of limestone, at which time the driller (if he is lucky to have reached this depth safely) will be glad to pull out and call it done.

"It is true, however, that at time these elevations are so slight that the 'wild catter' often confuses them with the local phenomena of the ant mounds and feels warranted to drill anyway, and we have instances on record where he eventually hit the apex of a hidden dome, as it happened, for instance, at Batson Prairie, Texas, whereby he obtained economic results.

"Undoubtedly there are many such hidden domes scattered over this vast area, and I make a passing reference to the possibility of their existence in order to point out the hazard of hitting any as very great.

"We will now proceed from New Orleans westward, and come upon "Belle Isle," the first of a series known as the five Salt Islands.

"These islands are of limited area, or from 250 to 1200 acres in extent and rise abruptly out of the surrounding marshes at an elevation of from 60 to 200 feet. They have all been explored and salt found thereon except 'Cote Blanche.' . . .

"The salt of all these domes is of remarkable purity (98 to 99 per cent. sodium chloride) except perhaps at Belle Isle, where part of this salt mass is saturated with petroleum. Following the contour of this dome by drilling near the apex, and while sinking a shaft the occurrent of galena and sphalerite was ascertained. The crystals are all sharp, and show no sign of erosion. Dr. A. C. Gill, of Cornell University, states that the galena shows no silver and the probability is that it represents a deposition from salt water by chemical action.

"The borings made at Belle Isle for oil and sulphur have disclosed lenses of considerable limestone and sulphur, and pools of water escaping from some wells are strongly charged with H_2S and SO_2, and yet the oil recovered from these wells gives no indication of containing sulphur in any form. This oil is parafine base, of 45 degrees Beaume, and has the appearance of being like Pennsylvania crude, only somewhat lighter in color still. Upon submitting a sample of this oil to the Standard Oil Company officials it was difficult to convince them that this oil had not already been refined in whole or in part.

Further explorations on this island have been suspended, as it was found unpractical to work the same for oil or salt. Grand Cote and Petite Anse are now producing a superior quality of rock salt, most of which is shipped to the Northwest in competition with the Michigan and New York salt.

"Anse La Butte, six miles north of Lafayette, is also a salt dome of limited area, which, however, has so far produced a few good oil wells. The oil carries some sulphur and is of 21 degrees Beaume, and is used principally for fuel.

"The Jennings field, on which oil was found at 1800 feet in considerable quantities, is also a dome, but so far no salt has been found thereon. It is believed by Professor G. D. Harris, of Cornell University, who for years has carried on most thorough and indefatigable work on the coastal plain of Texas and Louisiana that larger oil resources lie beyond the limit of the proven field.

"Of smaller importance is the field of Welsh, which is producing, however, an excellent grade of oil, but so far no salt-rock has been found, and the wells as a rule yield the best result at about one thousand (1,000) feet. This field gives no indication on the surface of primary or secondary doming.

"The oozing of petroleum and escape of gas at Bayou Choupique, now known as the sulphur mines, led the Louisiana Oil Company to drill for oil in 1868, and after going through the clays and sands of the Pleistocene, the quicksands and gravels of the Columbia to 443 feet, entered a gray massive limestone of about 60 feet in thickness. Under this, almost pure alternate layers of sulphur and limestone were found for a thickness of about 260 feet; below this lie the gypsum beds, with occasional layers of pure sulphur. It remains to be proved by deeper drilling if this dome is also underlayed by rock salt. The geological age of this dome has been ascribed by Hilgard as cretaceous, by Harris as eocene. The fossils, as classified by Ban Ingen, are of tertiary, and by Dall and Aldrich, of miocene origin.

"A new company was organized by General Jules Brody to win this sulphur by sinking an iron ringed shaft, and after

reaching a depth of one hundred and ten (110) feet the shaft was abandoned on account of a break in the lining and the asphyxiating of several miners by sulphur gas."

Captain Lucas then gave an account of Mr. Frasch's work and successful solution of the problem, which has already been fully covered in the preceding pages. Captain Lucas continued:

"Since the advent of the sulphur, no serious attempt has been made to explore the sources of heavy oil that still flows from the upper layers of some old test wells, except by the Beaumont boomers in 1901, and I am of the opinion that if Mr. Frasch was to make a serious attempt he would succeed, not only to get the oil in gushers, but also little Chinamen with firecrackers from the lower regions.

"Numerous attempts have been made to explore the 'Vinton Dome, about fifteen miles west of 'Sulphur,' but progress was impeded principally owing to the heavy gravel and quicksand beds of the Columbia, until about one year ago the many

FIG. 7.—LOADING SHIPS WITH SULPHUR AT SABINE, TEXAS. CLAM-SHELL DREDGES DELIVER SULPHUR ON 10 BELTS WHICH CARRY IT INTO THE SHIP.

efforts have been crowned with success. The Vinton field now furnishes considerable oil of about 21 degrees B., which carries about half per cent. sulphur.

"You have all heard from the fields of 'Spindle Top,' 'Sour Lake,' 'Saratoga,' 'Humble,' etc. They are also salt domes, and have produced great quantities of sulphur oil of an average specific gravity of 22 degrees Beaume, and Spindle Top alone is credited with about forty-three million barrels of oil to date.

"On Spindle Top was made the first discovery of sulphur oil of the coastal plain on January 10, 1901. It is also a salt dome and lies at an elevation of only 12 feet from the surrounding prairie, the surface of which contains about 235 acres only. Explorations had been made in 1882, 1885 and 1888 in search of sulphur or oil, but owing to alternating beds of quicksand and gravel of the Columbia, it was found impossible to go deeper than 300 feet, until in October, 1900, I made the second attempt, and after going through irregular alternating beds of clays, sand, gravel, lime, calcite and sulphur, reached the oil rock at 1120 feet depth. The pressure of gas and oil was so great that the four-inch drill pipe was shot out to a great height, carrying the head block, swivel and cable with it. Then a great rush of mud and water came out (the water used for drilling) followed by the ejection of large fragments of dolomite and fossils. It settled then to a steady flow of oil to a height of about 200 feet through a six-inch pipe. The well flowed continuously for ten days, when it was finally closed by an eight-inch gate valve. This oil was heavily saturated with H_2S and SO_2 and was very offensive to the nose, while the well was in eruption, as within a radius of several miles all houses painted with white lead were blackened, also the silver in houses, and even to the silver coins in circulation. It was estimated that this well flowed in ten days while in eruption about 750,000 barrels of oil. The oil rock is a porous dolomite carrying some sulphur in crystals and containing considerable calcium over magnesium.

"The size of the cavities into the dolomite can only be estimated by the large fragments shot out from the wells while in eruption. Drillers, however, reported instances of their tools dropping for several feet, leading one to conclude that the oil rock is cavernous, which in consequence made an admirable storage reservoir for the oil. The actual thickness of the oil-bearing rock is undetermined, but it has been estimated to be from 75 to 150 feet thick. A test well drilled near the discovery well entered gypsum at about 1200 feet and at 1650 feet encountered rock salt, which continued to a depth of 1900 feet, when the drilling stopped.

"The discovery of this oil pool started a celebrated boom in Texas and Louisiana. Many men and women with speculative oil tendencies were stirred up from Mexico to the Appalachians, with Spindle Top as an objective centre. The mere fact of land being in the vicinity of Beaumont sold it at fabulous prices, while fractions of an acre on Spindle Top sold at the rate of $760,000 per acre. Not that there was any value thereon warranting such prices, but that it enabled the boomer to capitalize his twenty-five by thirty feet of land, near a known gusher, at millions of dollars. However, by the time he was through with the sale of his stock, widely advertised, a well

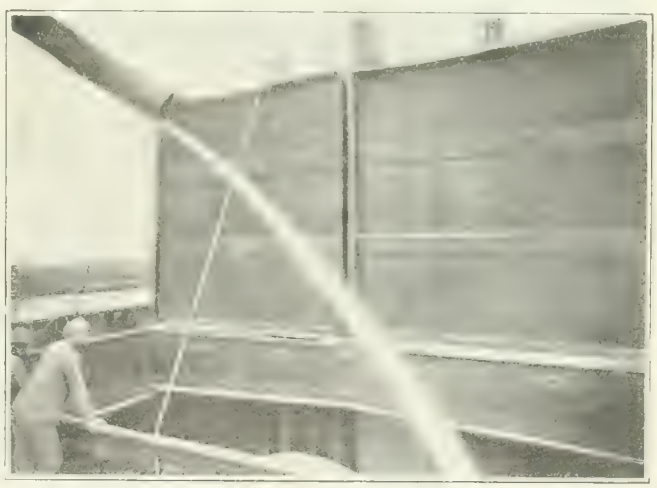

FIG. 8.—S. S. MELROSE RECEIVING LOUISIANA SULPHUR BY MACHINERY AT THE RATE OF OVER 10 TONS PER MINUTE AT THE UNION SULPHUR COMPANY'S DOCKS IN SABINE, TEXAS.

came in dry and the boom collapsed, and so did most of the many hundreds of companies capitalized at enormous figures. Had Spindle Top been sanely exploited by experienced drillers, I am confident that it would gush to-day.

"Still traveling westward we come upon other domes, such as 'Hoskins,' 'Bryan Heights,' 'Big Hill in Matagorda' and 'Big Hill in Jefferson County,' 'Damon,' 'Kyser,' 'High Island,' 'Barber Hill,' etc., all of which have been explored, but so far have been found barren in whole or in part.

"High Island and Damon Mound, two interesting elevations of 50 to 100 feet above the surrounding prairies, and of about 3,000 acres in extent each, have practically the same characteristic indications that Spindle Top had, to-wit: The elevation above the prairie indicating a possible dome, the sour water, the springs charged with the hydrogen sulphide, the gas escape, etc. The opening of a well, drilled by hand at High Island in search of water, was plugged with straw, and a few years later the plug was extracted and found to be a solid mass of sulphur; yet after repeated drilling to a considerable depth on this Island and Damon Mound, nothing of commercial importance was found. The drill passed through alternate beds of quicksand, silicious clay, sulphur and clay, some oil and salt at bottom.

"At Big Hill, Jefferson County, Texas, also an attractive possibility for an oil proposition, solid dolomite was found at 350 feet, which continued to a depth of 1400 feet.

"At Bryan Height a great gas pressure was encountered in 1901 charged with hydrogen sulphide, but it was subsequently abandoned. Big Hill, Matagorda County, had a small production. The oil was found at depths of 885 to 1050 feet, in limestone which possesses the same characteristic features of the oil-bearing rock of Spindle Top. As much as 60 feet of solid sulphur was reported from some wells, and always near the oil horizon. The oil was proportionately charged with it, and the gas, chiefly H_2S mixed with SO_2.

"In conclusion I would say that the Domes of the Coastal Plain have broken the world's precedents. First, for the limited area, second, for the productiveness as yet developed, and this holds good for sulphur, oil and rock salt, which goes to the credit of the Coastal Plain only.

"There are other richly productive fields of somewhat older geology, but want of time precludes me from describing them.

"By glancing at the map you will note that the Southern Pacific Railroad found itself to be located on to every field as fast as discovered, and I was told by a 'wag' that when the Almighty created the Universe He also located this railroad, and at once got busy to provide material for this road to haul, and that is the reason why He placed the sulphur deposit and oil pools and the rock salt adjacent to its line. This road was the first one to utilize this cheap and convenient resource as fuel and this at a minimum cost.

"He then improved and grew magnificent forests of timber also adjacent to this line, and then prepared the soil for the unexcelled culture of rice and sugar.

"The whole of these enormous commercial resources were placed by Him, so to speak, in the front yard of this fortunate railroad, and without the expenditure of a dollar for their advertising bureau, so that I feel justified in concluding to call the foregoing the Economic Geology of the Southern Pacific Railroad."

After the formal conclusion of the meeting many of those present remained together informally examining Mr. Pough's sample exhibits, while Mr. Frasch was kept busy in shaking hands with his many admirers. Altogether it was a most enjoyable evening.

Hardness of Plasters and Cements, and a Simple Chronographic Apparatus for Recording Set*

By Dr. Chas. F. McKenna.

One cannot give a clear definition of the term "Hardness" which shall serve for all the meanings in which it is used. The mineralogist using Moh's scale always means by this a measure of resistance to scratching or abrading; the wood-worker means the resistance to cutting; the steel-maker sometimes means by it the resistance to deformation under applied loads; in fact, indentation tests rule in many fields rather than scratching, cutting, or any other form of test.

In the case of hydraulic cements, the first stages of hardening have been usually measured by resistance to penetration; the later stages by finding the increase of cohesion determined by resistance on uniform cross-section to tractive or compressive forces gradually applied until rupture occurs.

The *setting* of plasters and cements is the very first stiffening and rapid development of cohesion up to the stage where needle-points under moderate pressures do not penetrate the surface, or where small test objects are easily handled without fracture. Beyond this the phenomenon, in which the cohesion due to complex mineral-forming reactions is step by step increased until a considerable age is reached, is called the *hardening*.

*A paper presented at the Washington meeting of the American Institute of Chemical Engineers on Dec. 21, 1911.

The chemical phenomena occurring in the setting of plaster of paris are chiefly those due to the energy in supersaturated solutions. Where a small proportion of water is used a hydrated sulphate of lime of one form goes into solution and the concentration causes the settling out or solidification of another form of hydrated sulphate; the water released from this helps to dissolve more of the first form, which, by concentration, duly deposits again, and thus the process is continuous to total solidification. Similar phenomena can be observed in supersaturated solutions of some salts, which can be caused to deposit crystals and thicken almost to total solidification. The setting of such a compound of hydrated sulphate of lime is rapid, and except for effects of drying, the maximum hardness is obtained a very few hours after the gauging.

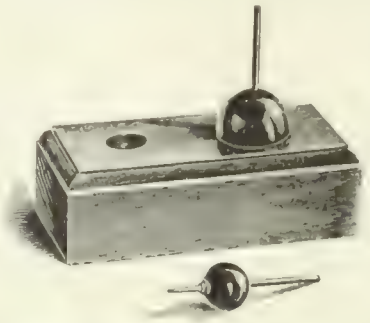

FIG. 1.—GILLMORE APPARATUS.

In the setting of hydraulic cements we have something much more complex, though we have been instructed by the case of plaster and by some of the points of similarity in it.

Powdered Portland cement clinker is a complex solid solution of silicates and aluminates rich in lime. When it is wet the alkaline lime solution resulting reacts on the silicates, producing a colloidal mass. A thermal effect occurring here in the beginning is the absorption of heat due to solution or the passing of the solid salts into the ionic condition.

In the setting of cement the first gelatinous mass formed is less and less permeable, due to drawing away of water coincident with the lowering of temperature; then as the crystal formation begins, the proportion of free water momentarily increases again and softens the colloids. Later the full interlacing of crystals and the drying of the colloids admit less and less of penetration, and thus we have the development and finally the end of the process of setting.

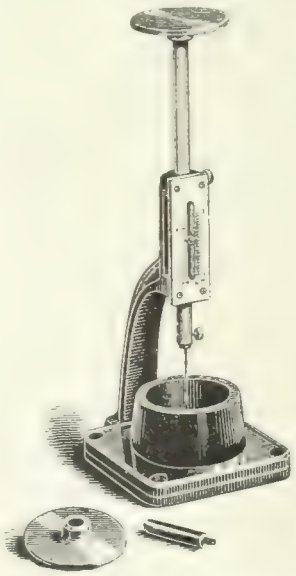

FIG. 2.—VICAT NEEDLE

Hardening can then go on through further molecular interchanges leading up to the formation of silicates of lime and alumina analogous to some of the hydrous silicates of mineralogy.

According to Michaelis the exact steps are described as practically a migration of water throughout the mass. The first particles of clinker are dissolved on the surface, the supersaturated lime solution thus formed reacts to form a gelatinous mass, and when crystals of aluminate of lime are formed the water separated goes further to attack newer particles of the clinker nodule, later deserting the colloids formed and passing into the air or into the water in which it is immersed.

These reactions are complicated again by the presence of sulphate of lime, which serves to form with the aluminates of lime a double compound of slow setting qualities, neutralizing the usual effect of a cement rich in aluminates of lime, where the setting is very quick and the development of heat sudden and great. Thus you will observe we consider setting to be consequential upon the formation of both colloids and crystaloids.

Apparatus for observing these changes in the setting process have usually been simple. For expert workers it suffices to use the thumb-nail. With skill and accustomed observation they thus obtain a definition which is as remarkable as the means are simple. Nothing has been developed toward providing means for observing set in plaster of paris; the contraction and dilatation, however, have been observed by Vant Hoff in a beautifully simple apparatus.*

General Gilmore recommended, for observing set in Portland cement, a weighted coarse wire and a more heavily weighted fine wire (Fig. 1) for the determination, respectively, of the first stiffening (initial set), and the firm resistance to any penetration or deformation (final set). Neither of these methods is instrumental or fitted to record distinct differences.

The first apparatus designed for such a purpose was that of Vicat, the French chemist and authority on cements. The Vicat needle (Fig. 2), is a weighted one, cylindrical and 1 square millimeter in area on the face, moving in a vertical scaled-off guide and falling upon the mass of gauged cement in a mould below. The initial set is taken as the time at which the needle will not penetrate within a certain distance of the bottom of the mass, and final set as the time when there will be no mark upon the surface from the needle.

However, chronographic and automatic apparatus have been sought for.

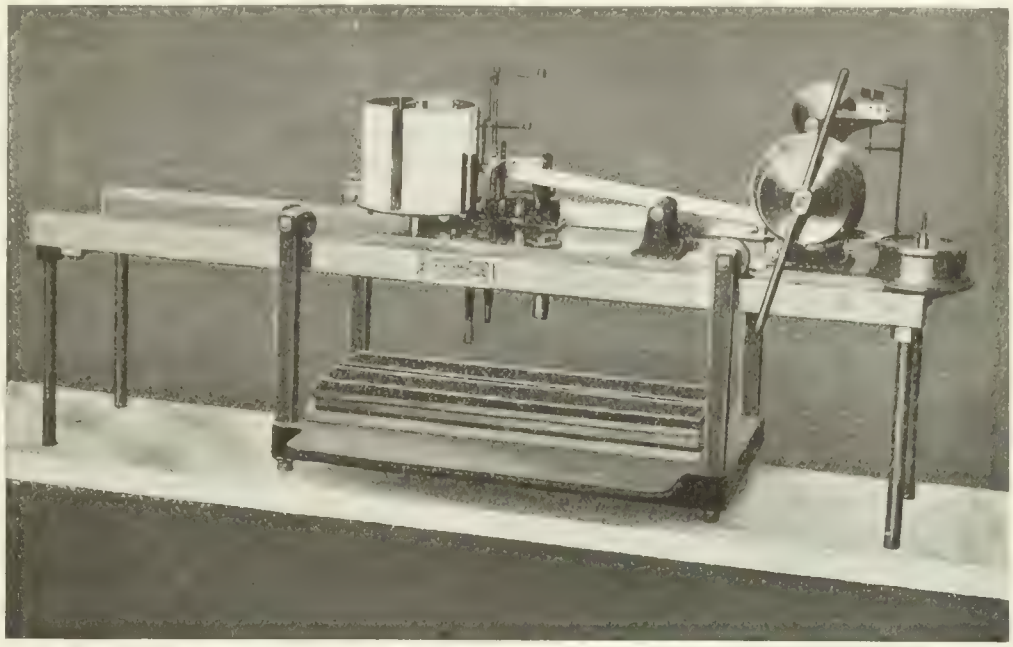

FIG. 3.—AMSLER LAFFON CEMENT SETTING RECORDER

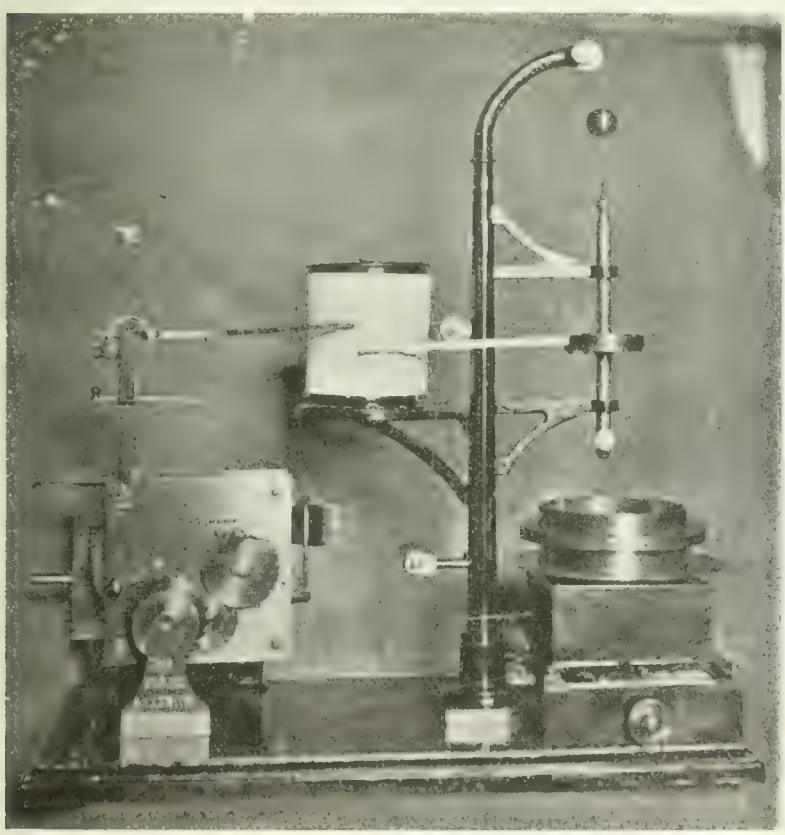

FIG. 4.—NICOL SPISSOGRAPH.

Professor A. Martens, of Charlottenburg, designed an apparatus in which needles energized by magnets are dropped and raised again as a clock movement makes the contacts.

The Amsler-Laffon cement setting recorder, Fig. 3, has been used in Europe. This is described in the journal *Cement*, from which the accompanying cut it taken, and the following description: In testing the activity of cements by this apparatus two moulds are filled with a plastic paste and two needles are lowered upon the cement at different intervals, penetrating more or less into the mortar according to the progress of setting. The depth to which each needle enters the mortar is recorded on a drum by two separate pencils. After each strike of the needles the drum turns a little and the table on which the moulds rest advances a step from right to left. The needle holders are lowered and raised by lever, which is set in motion by a spiral spring; a clock movement lets loose a governor and stops it again when the strike of the lever is completed. The diameter of the needle is 1 mm. Each needle holder weighs 300 grams.

The Nicol Spissograph, Fig. 4, the invention of R. Gordon Nicol, of Aberdeen, Scotland, and made by A. & J. Smith, of that city, is similarly designed. This apparatus consists of a clockwork which raises and lowers every three minutes a pointed needle; at the same time the paste is rotated in a spiral to present a different spot to the needle at every contact. On the apparatus is a thermograph recording on the same chart the temperature of the air at the time the test was made. The whole is covered with a glass case and arrangements are made to keep the temperature and humidity regular.

One of the best achievements in this line has been Gary's apparatus and the resulting investigations. He used the thermal changes during setting as the basis of study, and by photographing the changes of the mercury columns secured data

*Z. Physik. Chem. 70-146.

chart. Such a record as was thus secured, Fig. 5, gives admirable indications of the energy at work. None of these automatic instruments has been used in this country as far as I know.

The following is an extract from the official report of R

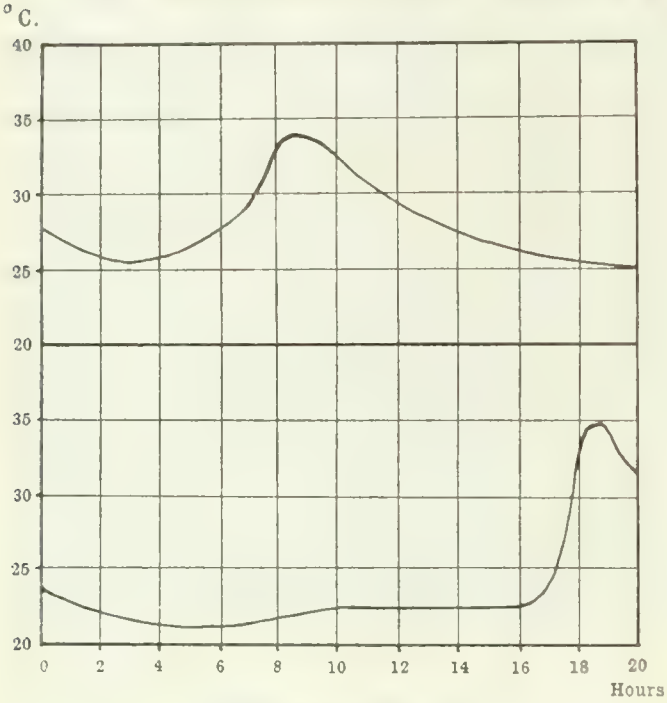

FIG. 5.—RECORD OF CARY

Feret, Boulogne-sur-Mer, at the Fifth Congress of the International Society for Testing Materials, held at Copenhagen in 1909.

Duration of Setting

"The use of the Vicat Needle continues to be the only practical method in use for the determination of the duration of the period of setting of hydraulic cements. The appliance is of extreme simplicity, but its readings are sometimes uncertain, especially when it is a question of determining the end of the period; besides, the readings are of a purely conventional character and do not appear always to bear a sufficiently constant relation to the duration of the setting period of the mortars of actual practice. The discovery of more exact methods has therefore been attempted. Methods of testing based on the measured variations in the electric resistance of mortars while hardening have not given results of interest.

"Other investigations have aimed at the definition of the setting by the determination of the temperature of the mortar during its continuance. Reasonably regular curves were obtained by this method, which, however, were dependent on the testing conditions and corresponded with chemical phenomena, the relation of which to the change of consistency called setting has not yet been quite clearly established.

"The principal nature of the method to be employed may be the ascertainment of the time, reckoned from the commencement of the gauging, during which a given mortar can, with impunity, be further used without having to be revived by a fresh addition of water or a too violent mechanical treatment."

Reading this I was led to take up again certain studies of setting which I had made some years before, in which I was observing the resistance to penetration by glass rods, and the resistance to withdrawal of glass threads progressively acted upon by the salts and compounds formed in the paste and operating during the setting process. I thought that the holding power of newly formed salts upon glass might be progressively observed. Also it seemed to me then that the testing of the surface by wire points showed a lack of effectiveness in determining set in colloids and crystallo-colloidal binding agents. Penetration along a plane similar to shear by a knife blade should give better results than mere resistance to rupture of a surface at one point, just as the cutting of metal by a turning tool affords a better test of cohesion than indentation or scratching does.

If several glass rods or pins, ten or fifteen-thousandths of an inch in diameter, are driven into soft paste of plaster or cement, and at intervals are tipped forward, they will cut the mass at first considerably; later to a diminishing extent; and finally when the colloids and crystals are both well formed about the pins (a period corresponding with the final set or resistance to the light wire heavily loaded), they snap off sharply and suddenly. Such a combination seemed to give indications of very fine and measurable differences.

Now, if you were to bring up against a line of such pins a glass rod which had been smoked, you ought to get markings on it making a record showing relatively the resistances to penetration.

It seemed to me that this afforded a means of operating a graphic and chronological method, and I have made many models of apparatus for such a purpose by making simple adaptations of things at hand till the present model was developed and put lately into this final form by Messrs. Schneider Bros., of Jersey City, the gifted mechanicians who are known all over the world for the simplicity and beauty of their work on scientific instruments.

I will explain in as few words as possible the operation of this instrument, Fig. 6. It consists of a screw *H* operated by clockwork, giving two speeds, there being a shifting lever *L* for a speed of 1 in. an hour and another speed of double that. It can also be operated by hand through a knurled head at one end. This screw *H* carries a moving finger *F* projecting over a long rectangular paste mould *C*. This moves forward and strikes successively the glass pins *P* inserted deeply into the paste and projecting vertically from it in one line. As each glass pin bends forward it bears against a smoked glass rod and traces its path until when a distinct resistance is attained it snaps off. Back of this is an adjusting frame to carry the glass rod, and this can be brought forward very delicately, or drawn back, by the aid of a fine adjusting screw

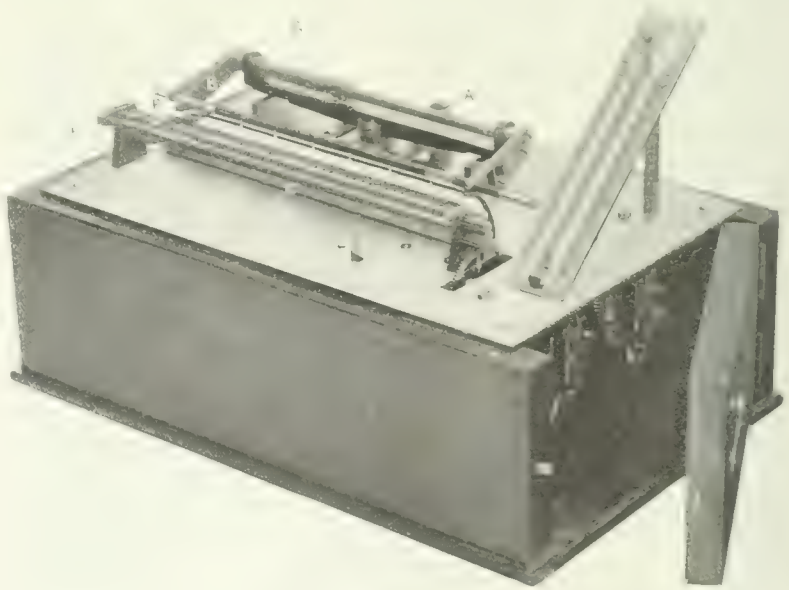

FIG. 6.—MCKENNA RECORDING APPARATUS.

A at the back. A metal mould is filled with freshly gauged cement and run into place between the screw and the adjusting frame. The glass rod which has been previously smoked and then rubbed clean over one-half of its surface, is inserted in the frame and brought forward over the center of the paste so that against the clean part of its surface these little pins are guided by it as they are inserted. So far as my investigations have gone I find that fifteen one thousandths of an inch (.015") give strength enough for meeting resistance, at the same time giving a tendency to snap. They are pushed in vertically along the middle line ½-in. apart; the glass rod is drawn back by the screw *A* and the untouched smoked part is turned over so that it can be brought up against the pins by the screw again, ready for any record. Then the clock is started, the finger begins to move, and as it strikes each pin successively it makes the respective record of the resistance to penetration at that point and time. A maximum and minimum thermometer may be attached to the base plate.

When everything is thus arranged the top glass case can be put over it, leaving a small dish of water in the case, and the whole may be left, for instance, over night. In the morning the entire record is on a glass rod. Records thus made resemble somewhat the markings in Fig. 7.

(The record given for plaster of paris is not symmetrical as to time, as the record shows.)

These glass rods, with the records upon them, can be varnished and preserved for examination at any time, or the record can be photographed on sensitive paper and thus preserved.

From plaster of paris I obtained a simple record of differences in resistance to penetration. I have not had many opportunities to experiment with varieties in this substance, but I expect to find that the instrument will readily indicate the differences due to changes in percentages of water, catalytic agents, etc.

From Portland cement the first few records already obtained are most interesting. It seems that in every normal Portland cement I have thus tested there is observable in or about the third hour an indication of a relaxation of the stiffness first obtained and then a resumption of hardening. Comparing these results with those of Gary's thermal studies, it is seen that he observed a marked lowering of temperature at or about the third hour. If we consider again the most modern theories of setting, I think we can explain this. The cooling effect of course is at the period when salts are going into solution most rapidly.

It is well known that if a break occurs in a temperature-solubility curve which is otherwise continuous, it is a proof that the solid substance which is in equilibrium with the solution has passed into another form at the temperature of the break. We have the reverse of this in our record of cohesion, namely: the break in continuity of the marks of increasing cohesion indicates the separating out from a saturated solution of a greater proportion of still another component, and that the water thus freed permeates the colloid and softens it. Later, by dessication, by absorption of the water within and further crystallization, cohesion begins to increase and impenetrability and hardness go on. The discovery of this slack period or reverse set explains contradictions experienced in the past in measuring or determining the initial set by the surface penetration system. It probably also will explain anomalies occurring in the practical use of cement during the first hours of gauging fresh cement.

If this observation of change in the order of setting should prove to be universal for cements with the sulphate of lime additament, we may have to observe first *initial set*, then *reverse set*, and lastly *final set*, and distinguish between them in time and character.

It is my intention to continue work as opportunity presents on this instrument, which appears to be simple and useful, and in time we may hope to reach a little further in our knowledge of the setting of plasters and cements.

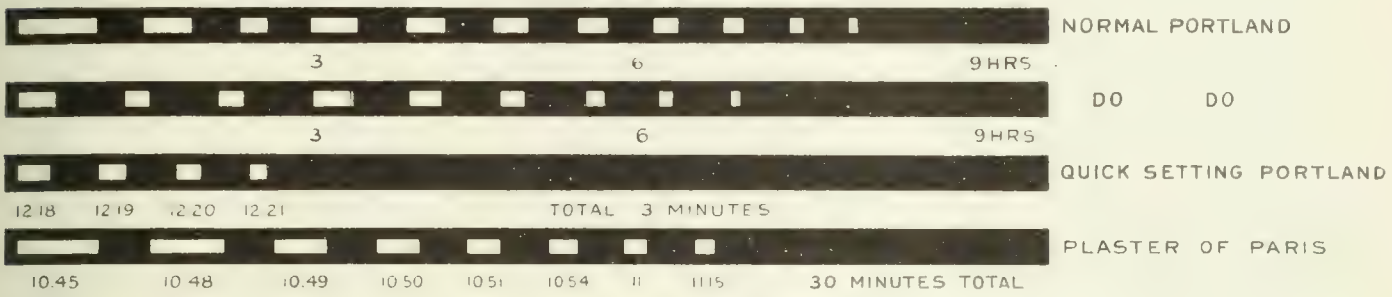

FIG. 7 COMPARATIVE RECORDS

Chemistry and Metallurgy in Great Britain.

(From our Special Correspondent.)

1911—A Retrospect.

It is rather difficult to review the year now closing, for it has been of an unusually variegated character. On the one side the pomp and splendor of state ceremonies—on the other political stress and strife—outside our own bounds vexed questions of international polity with the war dogs of all Europe straining at their leashes—at home great trade activity, with labor unrest, rioting, the use of troops.

All of these divergent forces must have their after effects, and we cannot enter on 1912 with a wholly clean slate. Internationally the rivalry in naval armaments has not yet reached its culmination. Industrially, we have at the moment of writing a big lockout in the cotton industry on a matter of principle which, if continued, must react on the local engineering and chemical trades. If very lengthy it will incidentally influence the price received for raw cotton in New Orleans. Of still greater moment is the risk of a big coal strike in eight or nine weeks' time. Yet in spite of all these troubles past and potential, trade has been and is phenomenally good, unemployment (other than that due to industrial disputes) has reached a minimum, and large engineering works are booked up with from six to twelve months' work.

No epoch-making inventions or discoveries will seemingly be associated with 1911 so far as chemistry or metallurgy are concerned. A steady progress toward commercial success has characterized chemical and electrochemical firms alike. Improvements in the price of copper must react favorably on the aluminium industry.

As regards the electrolytic alkali processes, the Castner-Kellner concern is phenomenally successful. The electric furnace is becoming better appreciated, but has not yet caught on to any large extent in this country.

The immediate future seems satisfactory in all spheres. Industrially we have plenty of work. Scientifically we are well occupied in perfecting processes and co-ordinating past discoveries and inventions. Financially the money market is easy. But at the back of this there are three realized factors, each inimical to peaceful progress. There is the danger (fortu-

nately less pressing than four months back) of a titanic struggle in the North Sea for the maintenance of our Empire. There is a world-wide rise in food prices, depressing the food-wages of the worker, and there is the labor unrest partly engendered by these high food prices. With the times thus out of joint, we are blessed with too many well-meaning sentimental amateurs, each persuaded of his heaven-inspired destiny to set them right. But to mention even one of these would be out of place in this letter.

The Purification of Water by Forced Oxidation.

At Cardiff, Reading, Tunbridge Wells, and elsewhere, a new system of purifying water is in operation, with results which are apparently satisfactory. The "Candy" apparatus consists of a strong steel cylinder, the lower part of which contains the filtering media—fine silica grit, sand, and a special substance termed "oxidium."

The water to be purified is forced into the cylinder at a pressure of from 5 lb. to 25 lb. per square inch, according to the character of the water, and compresses the air in the upper portion thereof, thus increasing to a considerable extent the quantity of oxygen dissolved in the water; and, in cases of highly impure water, the air supply may be maintained at the necessary rate by means of a small force-pump. Under the ordinary conditions of filtration, water containing iron will retain practically all the iron in solution, and will subsequently deposit oxide of iron in reservoirs, cisterns, or other receptacles, in which it may be store, as a consequence of gradual absorption of oxygen from the air. But this new apparatus so rapidly affects the oxidation of dissolved iron compounds in the water that the water leaves the filter practically free from iron.

Organic matter, too, appears to be thoroughly removed by this apparatus. The cleansing of the filter is easily carried out by reversing the flow of water, and it is stated that the quantity of water required for washing does not exceed 0.75 per cent of the quantity filtered. With a filter 8 ft. 3 in. in diameter some 9000 gal. per hour can be dealt with; and the capital cost for the average sand filter is put at about £15 per 1000 gal. working capacity per day, while the capital cost of the apparatus under consideration is stated to be only from £3 to £4 per 1000 gal. working capacity per day. Working expenses are stated to show a similar saving, being put at 1s. per 1,000,000 gal. for the "Candy" apparatus, and at 3s. to 5s. per 1,000,000 gal. for ordinary sand filters.

An Oil Fuel Process for Steel Castings.

In a recent issue of the *Times* a correspondent describes the Stock steel process, which is especially suitable for the production of small and intricate castings, and has been in operation at several works in the north of England and at, at least, one well-known works near London for over a year.

It is essentially the Bessemer process, in which hematite pig-iron is first melted by a blast of a mixture of high-pressure hot air and oil directed on to the surface of the charge; hot air alone being subsequently blown under pressure on to the molten metal to remove silicon and excess of carbon.

The plant consists of an oval converter lined with firebrick, mounted with trunnions on a turntable revolving horizontally. After heating for about half an hour the converter is placed horizontally to receive the charge of pig, and is then moved a quarter-circle into the melting position. The air from the blast is heated to about 800° Fahr., and has a pressure of ¾ lb. per square inch. The time required to melt the metal is about 60 minutes, when the converter is placed in a vertical position and the oil supply stopped.

A blast of hot air, at a temperature about 150° lower than that of the waste gases, is then played on to the metal and the slag removed. Silicon is got rid of by oxidation and the molten material consists of iron and carbon. Oxidation of the carbon now begins; the monoxide burns, and when the flame becomes dull, broken glass is thrown in to make a good slag and the air blast is shut off. The addition of ferro-manganese or spiegel, in quantity sufficient to act with the residual oxides, is made, and the metal is rabbled for pouring.

As a consequence of the efficient utilization of heat from the waste gases the molten metal attains a very high temperature, and the consequent liquidity permits a ready combination of alloys to produce special qualities of metal. The castings can be made in intricate molds, and do not need annealing. They show a high tensile strength and very good elongation. Allowing 13 per cent for loss in conversion and 3¼ per cent for spillings, etc., the cost of the molded metal is said not to exceed £5 per ton when hematite pig is employed, and the cost of electric power for a blower consuming 42 units is not more than 0.6d. per unit

Market Prices, December, 1911.

Copper has shown a decided upward tendency. Opening at £59 it had risen to £60.15.0 by the 12th, and £62.5.0 by the 18th. Though a slight decline then set in, it closes at £63.10.0 in good demand.

Tin opened at £203, but took a sharp dip downwards from the 4th to the 11th, reaching £197 on that date. From the 13th it shot smartly up again and closes at £206.

Lead has been steady, if anything slightly inclined to go down. Opened at £16.3.0 and closes at £16.2.6.

Haematite has risen to much the same extent as Scotch pig, opening at 63/- and closing at 66/-.

Scotch Pig has been strong, rising from 54/- on the 1st to 55/8 on the 18th. Closes at 56/6.

Cleveland has followed the same course as Scotch pig, opening at 47/9 and closing at 50/8.

India Rubber opened at 4/4 and reached 4/5½, but has, on the whole, been steady and quiet. Closes at 4/3½.

Alum, lump, loose, per ton	5.12.6

Sinter-Roasting with Dwight-Lloyd Machines at Salida, Colo.

Editorial Correspondence.

The advent and success of the various forms of sinter-roasting, or blast-roasting, particularly in connection with western lead smelting, is a good index of a marked change which has occurred in the mining industry in the past decade. We refer to the decline in the production of crude ore suitable for direct smelting in the blast furnace, and the coincident increase in the quantity of concentrates produced.

The latter condition was the cause of some concern to smelters, for the major portion of ore offered was not in condition for blast furnace smelting, nor was this condition materially improved by roasting in hand reverberatory or mechanical roasters. The capacity of blast furnaces was reduced, and an excessive quantity of flue dust formed which was even more difficult to treat than the original fine ore. Briquetting of roasted concentrates and flue dust, with lime as a binder, was introduced at some plants in an effort to convert fine material into a suitable blast furnace feed, but this proved an expensive additional process and was never regarded as a good solution of the problem. The real need of the lead smelter remained unfilled until the sinter-roasting systems were developed.

The first of these to gain commercial prominence in the United States was the Huntington-Heberlein pot-roasting system, which was installed at the plants of the American Smelting & Refining Company. Like many inventions which are pioneers in their lines, the Huntington-Heberlein system did not embody all the virtues of sinter-roasting which have since been developed, although it was a great step in advance over forms of roasting used previous to its development. It had inherent disadvantages which were not fully appreciated until they appeared in actual practice, or were accentuated by the improvements made in other types of sinter-roasters. It was intermittent in operation; used an upward draft through a deep bed of ore; subjected the entire charge to the blast for a long period of time; and finally, produced a mass of sinter weighing from 6 to 9 tons, which required a great deal of labor in breaking it for the blast furnace.

In contrast to this process is that of Dwight and Lloyd, which was evolved in an effort to overcome the disadvantages of pot-roasting. The time of exposure to heat is short, and the possible loss by volatilization correspondingly small; the process is continuous and gives an evenly sintered cake which is suitably broken in its discharge from the machine; the draft is downward through a comparatively thin bed, thus obviating the production of fine unsintered ore.

In an interesting contribution to the School of Mines *Quarterly*, for November, 1911, Mr. A. S. Dwight compares the efficiency of various forms of roasters, taking as a factor the number of pounds of ore treated per day on a square foot of furnace hearth. The following table embodies his estimates of various forms of roasters.

Efficiency of Roasters

	Efficiency Factor, Pounds Ore Treated per Day per Sq. Ft. of Hearth
I. Roast heaps and stalls	5 to 20
II. Reverberatory roasters:	
1. Hand roaster	24 to 35
2. Mechanically stirred:	
average conditions	33 to 75
special conditions	150
3. Revolving cylinders	128
III. Blast roasting in pots	500 to 900
average	600
IV. Blast roasting in thin layers:	
1. Intermittent down-draft pans	1000 to 2000
2. Continuous sintering machines	2200 to 3000

Description of Salida Plant.

Different types of the Dwight-Lloyd machine have been invented, but the straight-line, continuous type is probably most familiar. At the Salida smelter of the Ohio & Colorado Smelting & Refining Company, three large, straight-line machines have been installed, in addition to a small one which was used experimentally. The accompanying drawing shows the general arrangement of the roasting plant.

The Dwight-Lloyd machine consists essentially of a traveling sectional hearth, feed hoppers, ignition furnace, suction box, fan, and driving gear, supported by a framework of structural steel. The hearth comprises a continuous line of forty-four sections or pallets, traveling around sprocket wheels at each end of the frame. The charge is delivered onto the hearth at one end, passes successively under the igniter and over the suction box, and is finally discharged as sinter at the other end. Each section of the hearth is 24 in. wide, 42 in. long and 4½ in. deep, and composed of three herring-bone grates each 8 in. by 42 in.

The grates originally provided with the machine were found too light, and breakage was excessive. Those now used are heavier, having only four-fifths as many slotted openings as the former grates, with a greater flare from top to bottom of slot. These grates have given better satisfaction, both as to durability and freedom from accretions which obstruct the draft.

The rate of travel of the hearth is regulated by cone pulleys. At maximum speed it moves at the rate of 1.6 ft. per minute, and at this speed the machine has a capacity of about 75 tons in 24 hours. The roaster foreman varies the speed according to the condition of the charge and the efficiency of the roast, basing his judgment on the appearance of the sinter as it breaks into cakes prior to being discharged. The cake should show that sintering has progressed down the grates.

The charge comprises both coarse and fine material, each being delivered from a separate hopper, the bottom opening of which is designed to deposit a bed of definite depth. The coarse material ranges in size from ½ to 1 in., and forms a porous bed on the grates about 1 in. deep, on which the regular charge is then delivered, giving a total depth of bed of 4 in. The charge is ignited from a suspended coal-fired stove in which a bridge wall directs the flame so that it impinges on the surface of the charge. The area exposed to ignition is 12 in. by 42 in., and the time of exposure averages from 35 to 40 seconds. Fuel consumption is light. At Salida one ton of coal will ignite 185 tons of charge, equivalent to about 11 lb. of coal per ton of charge. Gasoline burners were tried first, but proved unsatisfactory, particularly in igniting the charge at the sides of the hearth.

The moving hearth makes an air-tight joint with the suction box over which it travels. The size of the box determines the effective hearth area of the roaster, which is 42 in. by 264 in., or 77 sq. ft. At the ordinary speed of the hearth the charge is exposed to ignition and suction for 12 to 14 minutes. The efficiency factor of the roaster at 75 tons per day with a hearth area of 77 sq. ft. is approximately 1950 lb. per square foot per day.

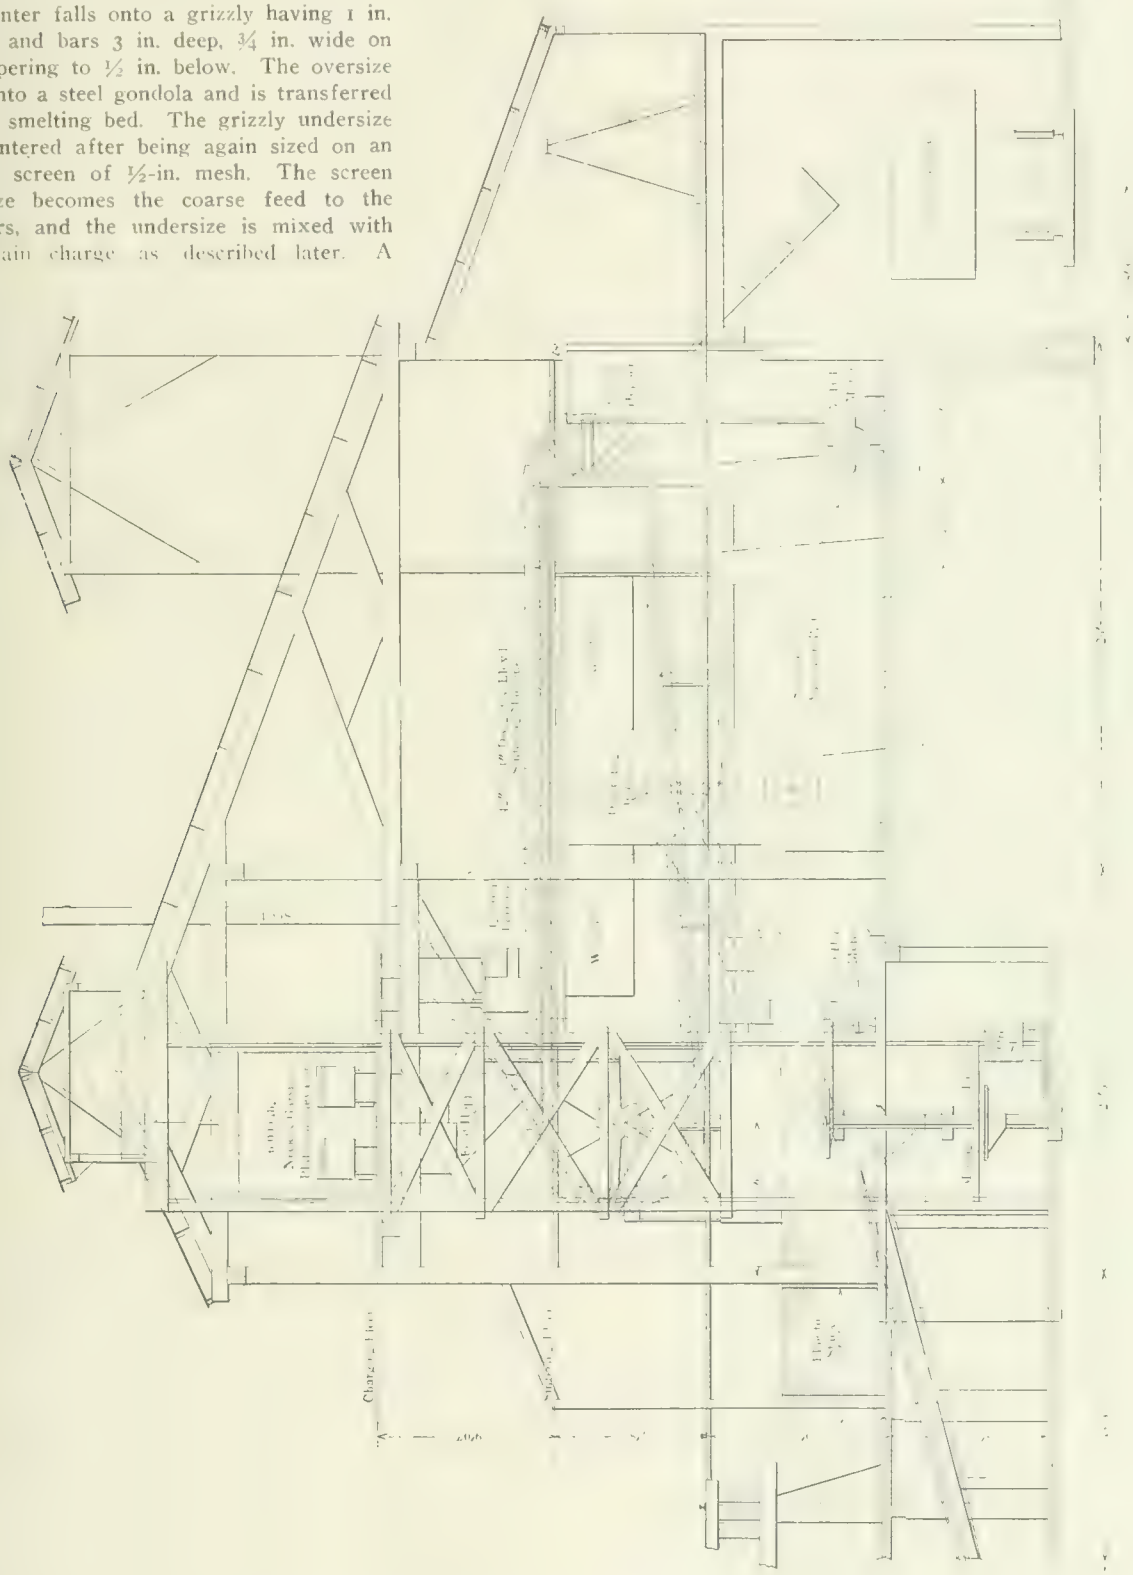
The fans used at Salida are specially constructed, being heavier and of better design than those originally installed. The old fans were mounted at one end of a shaft, the latter being supported in bearings at the other end. With this construction the fan easily got out of balance due to accretions which formed by the action of the roaster gases on the metal. The result was a high cost of maintenance and poor satisfaction generally. In the new fans the impeller is mounted centrally on a shaft which is supported at each end, outside and independent of the fan housing. The bearings are water-cooled, and rest on blocks of oak on concrete piers, the wood serving to give a slight flexibility to the construction.

The fans are 66 in. in diameter with impeller blades 7 in. wide. They revolve at 720 r.p.m., each being driven by a 50-hp motor. At this speed they induce a pressure of 4.6 oz. per square foot, equivalent to 8 in. of water.

In some installations, for example at Trail, B. C., described in this journal for August, 1911, page 405, one of the grate

END ELEVATION
PLAN VIEW
PLAN
LOWER CHARGING FLOOR
FRONT ELEVATION

sections is left out of the line, so that on arriving at the discharge end each pallet falls a distance of 2 ft. against the one preceding it, thus dislodging the cake. At Salida, however, the line of grate sections is continuous, and an attendant bars the cake from the grate. The sinter falls onto a grizzly having 1 in. spaces and bars 3 in. deep, ¾ in. wide on top tapering to ½ in. below. The oversize falls into a steel gondola and is transferred to the smelting bed. The grizzly undersize is resintered after being again sized on an impact screen of ½-in. mesh. The screen oversize becomes the coarse feed to the roasters, and the undersize is mixed with the main charge as described later. A maximum of 25 per cent of grizzly undersize is thus returned to the roadsters, the exact quantity depending on the conditions of the roast.



GENERAL ARRANGEMENT OF SINTERING PLANT

Components of the Roaster Charge.

The roaster charge is a mixture of the following ores and products:

(1) Partly roasted iron sulphide concentrate, containing about 15 per cent sulphur.

This iron sulphide concentrate is the product of three Godfrey rotating-hearth roasters used as preliminary desulphurizers of heavy sulphides.

(2) Raw lead concentrate.

(3) Raw silicious sulphide ore, low in sulphur and high in silica.

(4) Fine sinter returned from the impact screen.

These are the four components of the roaster charge.

The composition of the dry charge for the month of December, 1911, was as follows:

Lead	18.0 per cent
Copper	1.0 " "
Insoluble	24.6 " "
Iron	21.2 " "
Manganese	1.0 " "
Zinc	7.6 " "
Sulphur	15.4 "

Mixing the Charge.

The mixing device used at Salida is worthy of special mention as being automatic, accurate and adjustable in proportioning the several components of the charge. It was designed by Mr. F. D. Weeks, formerly superintendent of the smelter in Salida.

As illustrated on p. 88, it consists of a series of hopper bins, one for each kind of ore; conveyer belts, and a mixing table. The bottom of each bin is formed by a short belt-conveyer supported on rollers directly beneath the bin opening, and traveling around head and tail pulleys placed in front of and behind the bin, respectively. When in motion this feed belt carries from the bin a continuous layer of ore of uniform cross section, and discharges onto another belt-conveyer running at right angles to it.

The feed belt-conveyers travel intermittently, being actuated by eccentrics mounted on a shaft extending the length of the line of bins. The speed of this shaft is regulated by cone pulleys and can be varied from 20 to 80 r.p.m. The eccentrics have a throw of 4 in., which is never altered; but adjustments are provided on the eccentric rods whereby all or any fraction of the throw can be applied to the head pulley of the belt-conveyer, thereby imparting an intermittent movement to the belt.

The distance traveled by the belt at each throw of the eccentric may be varied from 2 in., at full throw, to zero; 3/32 in. being the shortest actual travel. By an arrangement of friction pulleys, all tendency toward a reverse travel of the belt is overcome.

Thus each feed belt-conveyer may be made to travel a variable distance with variable frequency, delivering from its corresponding bin a quantity of ore proportionate to the distance traveled per minute. For the convenience of the metallurgist and the guidance of the operator in varying the proportions of the charge, an indicator is attached to the head pulley of each feed-belt, consisting of a pointer moving across an arbitrary scale at each revolution of the eccentric.

The main belt-conveyer delivers the charge to a cast-iron annular mixing table, 8 ft. in diameter, revolving at a speed of 2 r.p.m. The belt discharges above the center of the table, and the falling ore tends to form a cone. Stationary vertical rabble blades spread the ore toward the periphery of the table where it is drawn off into cars and elevated to the roaster bins. A spray of water plays on the ore while it is being mixed, adding about 10 per cent moisture to the charge.

The use of sinter-roasting seems bound to increase for reasons already given. In fact, a smelter which is not equipped with some form of this process will find it increasingly difficult to compete with plants so equipped. The recent closing of a Colorado smelter may be assigned in large measure to inadequate means for treating concentrates. At Salida the blast furnace charge is now largely composed of Dwight-Lloyd sinter, and the effect on furnace capacity is very satisfactory. Two blast furnaces, one 44 in. by 144 in., and the other 44 in. by 180 in., are now treating 440 tons of charge in 24 hours, a record which would be impossible under present conditions without sinter-roasting.

We acknowledge the courtesy of Mr. F. D. Weeks, of the American Metals Company, and Mr. E. H. Laws, superintendent of the Salida plant, in permitting the publication of the drawings and data here given.

Geophysical Research.

By Arthur L. Day.

To write the history of the earth is a very different undertaking from writing the history of a people. In the latter case a diligent seeker can usually find some ancient monastery where far-sighted historians of an earlier generation have collected the more important records which he requires and placed them within reach of his hand. With the earth's history, which is the province of geology, it is another matter.

The great globe has been millions of years in the making, and except for a mere fragment of its most recent history it has had neither a historian nor an observer. Its formation has not only extended over an almost incomprehensible interval of time, but we have no parallel in our limited experience to help us to understand its complicated development and no system of classification adequate to the task even of grouping in an orderly way all the observed rock and mineral formations with reference to the forces which moulded them. And even if we could correctly interpret all the visible rock records, we are still quite helpless to comprehend all those earlier activities of the formation period whose record is now obliterated.

To the student of the earth's history, therefore, the problem of gathering and ordering such a widely scattered and heterogeneous collection of effects and causes is one of somewhat overwhelming scope and complication. In the industrial world a situation of this kind soon results in replacing individual effort with collective effort in the organization of a system of a scope more appropriate to the magnitude of the task. We are familiar with industrial organization and the wonderful progress in the development of American industries which has everywhere followed it. We are also familiar with organized geological surveys and the success which has attended them in geological and topographical classification. But the idea of organizing research to meet a scientific situation of extraordinary scope and complexity is still comparatively new. The very words science and research are still regarded as referring to something out of the ordinary, something to be withheld from the common gaze, to be kept hidden in a special niche, behind a mysterious curtain and served by priests of peculiar temperament and unpractical ideals. This is both disparaging to our good sense and prejudicial to the progress of knowledge. Scientific research is not a luxury; it is a fundamental necessity. It is not a European fad, but is the very essence of the tremendous industrial success of the last 20 years.

Professor Nichols, of Cornell, as retiring president of the American Association for the Advancement of Science, put the case in this way: "The main product of science (research) is knowledge. Among its by-products are the technologic arts, including invention, engineering in all its branches and modern industry." The idea of scientific research is therefore not less tangible than industrial development, or less practical; it is merely one step more fundamental; it is concerned with the discovery of principles and underlying relations rather than their application. This being true, research should profit as much, or even more, from efficient organization as industrial development has done.

Although this conclusion is making its way but slowly in American science, in geological research, where material must be gathered from the utmost ends of the earth and even from within it, and where nearly every known branch of scientific activity finds some application, there is a peculiarly favorable opportunity for organized effort which is already coming to be recognized. "So long as geology remained a descriptive science," says President Van Hise, of Wisconsin, "it had little need of chemistry and physics; but the time has now come when geologists are not satisfied with mere description. They desire to interpret the phenomena they see in reference to their

[1]Presidential address delivered at the 700th meeting of the Philosophical Society of Washington, November 5, 1911. From the Smithsonian Miscellaneous Collections, the Washington Academy of Sciences.

causes—in other words, under the principles of physics and chemistry. . . . This involves co-operation between physicists, chemists and geologists."

In a general way, physics, chemistry and biology have already supplied working hypotheses which have been used by students of geology to help in the examination, classification and mapping of the most conspicuous features of the exposed portion of the earth. The geologist has gone abroad and has studied the distribution of land and water, the mountain ranges, the erosive action of ice and of surface water and the resulting sedimentary deposits, the distribution of volcanic activity and of its products, the igneous rocks; or more in detail he has studied the appearance of fossils in certain strata, and has inferred the sequence of geologic time. The distribution of particular minerals and of ore deposits has been carefully mapped. Regions which offer evidence of extraordinary upheaval through the exercise of physical forces have been painstakingly examined and so on through the great range of geologic activity.

In a word, the field has been given a thorough general examination, but the manifold problems which this examination has developed, although early recognized and often the subject of philosophical speculation and discussion, still await an opportunity for quantitative study. They are often problems for the laboratory and not for the field, problems for exact measurement rather than for inference, problems for the physicist and chemist rather than for the geologist. This is not a result of oversight, it is a stage in the development of the science, first the location and classification of the material, then the laboratory study of why and how much.

Certain indications have led us to believe, for example, that the earth was once completely gaseous and in appearance much like our sun. Indeed, it possibly formed a part of the sun, but through some instability in the system became split off—a great gaseous ball which has cooled to its present condition. The cooling probably went on rapidly at first until a protecting crust formed about the ball, then more and more slowly, until now, when our loss of heat by radiation into space is more than compensated by heat received from the sun.

Obviously, the earliest portions of this history are and must remain dependent upon inference, but the formation of a solid crust cannot advance far before portions of it become fixed in a form such that further disturbance does not destroy their identity. From this point on the history of the earth is a matter of record and can be interpreted if only we have sufficient knowledge of the mineral relations through all the stages of their development.

It must have been a very turbulent sea, the molten surface of our earth upon which the rocky crust began to form. The first patches of crust were probably shattered over and over again by escaping gases and violent explosions of which our waning volcanic activity is but a feeble echo. If the earth was first gaseous, and the outer surface gradually condensed to a liquid, its outer portions at least must have been whirled and tumbled about sufficiently, even in a few thousand years (which is a very small interval in the formation of an earth), to mix its various ingredients pretty thoroughly. It has accordingly been hard to see just how it came to separate into individual rocks of such widely different appearance and character.

Of course, the number of its ingredients was large. We have already discovered 80 or more different elementary substances in the earth, and there is an almost endless number of more or less stable compounds of these. The freezing of an earth is therefore different from the freezing of pure water, but the freezing of salt water offers a clue to the explanation of the way in which the earth solidified as we find it. When salt water freezes, the salt is practically all left behind. The ice contains much less salt and the remaining water relatively more salt than before freezing began. Applying this familiar observation to the supposed molten surface of the earth as it begins to solidify, we have a suggestion of order and reason in its separation into so many kinds of rocks.

Now, it happens that in the recent development of chemistry much attention has been given to the study of solutions of various kinds, and a great body of information has been gathered and classified of which our observation upon the freezing of salt water is a simple type. Still more recently (quite lately in fact) it has occurred to many students of the earth that here lies not only the clue but perhaps the key to their great problem. If the individual components which are intimately mixed in solution separate wholly or partially in some regular way upon freezing—and nearly all the solutions which have been studied appear to show such segregation—we have a quantitative system which will probably prove adequate to solve the problem of rock formation, provided only that the experimental difficulties attending the study of molten rock and the complications imposed by the presence of so many component minerals do not prove prohibitive. This is a very simple statement of the point of view which has led to the experimental study of rock formation in the laboratory as a natural sequence to statistical study in the field.

Geophysics therefore does not come as a new science, nor as a restricted subdivision of geology, like physiography or stratigraphy, but rather to introduce into the study of the earth an element of exactness, of quantitative relation. It may include physics or chemistry, biology or crystallography or physical chemistry, or all of these at need. The distinctive feature of geophysics is not its scope, which may well be left to the future, but its quantitative character. The Geophysical Laboratory of the Carnegie Institution of Washington has entered upon some of the investigations suggested by this long preliminary study of the earth—the physical properties and conditions of formation of the rocks and minerals. The Department of Terrestrial Magnetism of the same institution has undertaken another—the earth's magnetism; the German Geophysical Laboratory at Göttingen a third—the earthquakes—and these will no doubt be followed by others.

The first effect of calling exact science into consultation upon geologic problems is to introduce a somewhat different viewpoint. It has been our habit to study the minerals and the rocks as we find them to-day, after many of the causes which have had a share in their evolution have ceased to be active—after the fire has gone out. If we attempt to reconstruct in our minds the operations which enter into the formation of an igneous rock or of a body of ore, we must infer them from present appearances and environment.

The experimental geophysicist, on the other hand, confronting the same problem, says to himself: Can we not construct a miniature volcano in the laboratory; can we not built a furnace in which an igneous rock can be formed under such conditions that we can observe its minutest change? He proposes to introduce temperature measuring devices and apparatus for the determination of pressure, to investigate the character of the surrounding atmosphere and the quantity of water vapor which may be present. He insists upon the chemical purity of every ingredient which goes into the furnace and guards it carefully against contamination. In these various ways he will undertake to ascertain the exact magnitude of all the causes, both physical and chemical, which have been at work in his miniature rock-producer, together with the physical characteristics of the product.

A very practical question now arises. Can he do all this successfully at the temperatures where the minerals form? We must press this question and insist upon a satisfactory answer, for it is by no means obvious that the relations which the physicist and chemist have established at the temperatures of everyday life—energy content, density, solubility, viscosity, dissociation—will continue to hold when substances are carried up to a white heat.

The substances, too, are different from those with which the chemist and physicist have been generally familiar. Instead of simple metals, aqueous solutions and readily soluble active salts, we encounter silicates and refractory oxides, inert in

behavior and capable of existing together in mixtures of great complexity. We must, therefore, extend the range of our physics and our chemistry to a scope in some degree commensurate with the wide range of conditions which the earth in its development has passed through. Let us follow for a little the actual progress of such an attempt.

The first step is to provide the necessary temperatures. Obviously, the common fire-clay crucible and the smelter's furnace with its brick lining will not serve us here, for all these are themselves mineral aggregates. The charge, furnace lining and crucible would go down together in a fall as disastrous as Humpty Dumpty's. But experiment has taught us that platinum crucibles, magnesia furnace tubes inclosing an electrically heated helix of platinum wire, and electric temperature-measuring devices, provide a furnace in which nearly all of the important minerals can be successfully studied, which is hot enough to melt silver, gold, copper, nickel or iron readily, and where any temperature up to 1600° C. can be maintained perfectly constant if need be for several weeks. All these temperatures can be measured with no uncertainty greater than 5° C. This equipment preserves the chemical purity of the mineral studied and enables the temperature to be controlled and measured at every step of the experimental work. Or an iridium furnace tube and an iridium crucible can be substituted for platinum, the magnesia supports can still be used and we have it in our power to go on to 2000° C., which is quite sufficient for all the more important minerals which we know.

The physicist has, therefore, found a suitable melting pot, and means of ascertaining what goes on within the pot; but he at once encounters another difficulty. Nature has provided us with relatively few minerals of high chemical purity. If a natural mineral is chosen for experiment, however typical it may be, several per cent of other minerals may be expected to be present with it, the effect of which is at present quite unknown. Now the first axiom of the investigator in a new field who desires to undertake measurements which shall have a real value is that the number of unknown quantities in his equations must not be greater than he can eliminate by his experimental processes; in other words, he must begin with conditions so simple that the relation between a particular effect and its cause can be absolutely established without leaving undetermined factors. Having solved the simple case, it is a straightforward matter to utilize this information to help solve a more complicated one.

If we would, therefore, reduce the mineral relations to an exact science, which is our obvious purpose, it is necessary from the outset to prepare minerals of the highest purity and to establish their properties. Having obtained such a pure mineral type, it may be, and often is, in the power of the mineralogist and his microscope to determine by direct comparison with its natural prototype the kind and amount of effect actually produced in the natural mineral by the one or more other minerals which it contains. We have, therefore, hardly started upon our investigation before the need of an organized system is demonstrated—first comes the chemist, who prepares and analyzes the pure mineral for investigation; then the physicist, who provides and measures the conditions to which it is subjected; then the mineralogist, who establishes its optical properties in relation to the corresponding natural minerals.

Having prepared such a mineral, of high purity and of known crystalline character, we can ascertain its behavior at the temperatures which must have obtained during the various stages of earth formation. We can study the various crystal forms through which it passes on heating and the temperature ranges within which these forms are stable; we can also melt it and measure the melting or solidifying temperature.

Another mineral, prepared with the same care and studied in the same way, may afterward be added to the first and the relation of these two determined. If they combine, heat is absorbed or released, and this quantity of heat can be measured, together with the exact temperature at which the absorption or release takes place.

If the mixture results in the formation of one or more mineral compounds, we shall learn the conditions of formation, the temperature region within which the new forms are stable, and the changes which each undergoes with changes of pressure and temperature, as before.

If the new forms show signs of instability, we can drop them into cold water or mercury so quickly that there will be no opportunity to return to initial stable forms, and thus obtain, for study with the microscope at our leisure, every individual phase of the process through which the group of minerals has passed.

Without complicating the illustration further, it is obvious that we have it in our power to reproduce in detail the actual process of rock formation within the earth, and to substitute measurement where the geologist has been obliged to use inference; to tabulate the whole history of the formation of a mineral or group of minerals under every variety of condition which we may suppose it to have passed through in the earth, provided only we can reproduce that condition in the laboratory.

During the past quarter of a century there has arisen in the middle ground between physics and chemistry a new science of physical chemistry, in the development of which generalizations of great value in the study of minerals have been established. As long ago as 1861 the distinguished German chemist Bunsen pointed out that rocks must be considered to be solutions and must be studied as such; but inasmuch as comparatively little was known about solutions in those days, and the rocks at best appeared to be very complicated ones, no active steps in that direction were taken during Bunsen's life.

But in recent years solutions have been widely studied, under rather limited conditions of temperature and pressure, to be sure, but it has resulted in establishing relations—like the *phase rule*—of such effect and far-reaching character that now, just half a century afterward, we are entering with great vigor upon the prosecution of Bunsen's suggestion.

It is now possible to establish definite limits of solubility of one mineral in another, and definite conditions of equilibrium, even in rather complicated groups of minerals, which enables us not only to interpret the relations developed by such a thermal study as that outlined above, but also to assure ourselves that only a definitely limited number of compounds of two minerals can exist, and that they must bear a constant and characteristic relation to each other under given conditions of temperature and pressure, and that changes of temperature and pressure will affect this relation in a definite and determinable way.

Physical chemistry not only takes into account the chemical composition of mineral compounds, but their physical properties as well, throughout the entire temperature region in which they have stable existence, and, therefore, furnishes us at once with the possibility of a new and adequately comprehensive classification of all the minerals and rocks in the earth

The value of an adequate system of classification appeals chiefly to those whose duties bring them into intimate relations with the subject matter of a science, but so much may appropriately be said that a consistent application of physical chemistry to the minerals may operate in the not far distant future to develop an entirely new conception of the science of mineralogy.

As the number and scope of such exact measurements increase we gradually build up what may be called a geologic thermometer. Just as the location of fossils offers a basis for estimating geologic time, it often happens that a mineral takes on a variety of different crystal habits, according as it happened to form at one temperature or another.

Quartz, for example, which is one of the commonest of natural minerals and one of the most familiar, undergoes two changes in its crystal form which leave an ineffaceable record. One occurs at 575° and the other at 800°. An optical ex-

amination of even a minute quartz fragment from the mountainside will reveal to the skilful petrologist whether the crystal formed at a temperature below 575°, between 575° and 800°, or above 800°. And if we could have at our disposal a great body of such exact measurements of the temperature region within which particular crystals originate and remain stable, we could apply that directly to terrestrial formations in which this mineral occurs, and read therein the temperature which must have obtained during their formation.

All this will not be done in the first year, and perhaps not in the first decade; but the ultimate effectiveness of this method of procedure in establishing the relations between the minerals and the valuable ores is now as certain of success as the operations of any of the sciences which have now come to be characterized as exact, as opposed to descriptive.

There is one important difference between the great laboratory of nature and its feeble human counterpart. Nature operated with large masses, mixed with a generous hand, and there was always plenty of time for the growth of great individual crystals, at which we marvel whenever we encounter them, and which we have sometimes come to regard highly as precious stones.

To carry these processes into the laboratory is necessarily fraught with certain limitations. The quantities must remain small and the time and available financial resources will always be limited. So long as we are able to ascertain the optical character of a crystal with equal exactness whether the crystal is of the size of the proverbial mustard-seed or a walnut, the scientific laboratory cannot properly afford the time necessary to produce the large crystals which nature offers so aboundantly.

Furthermore, the crystals of nature often owe their brilliant coloring to slight admixtures of impurity, which, to the scientific laboratory, spell failure and are avoided with the utmost care. Most of the mineral crystals, when reproduced in the laboratory, are quite colorless.

And so, although the question is often raised whether we are not really engaged in the artificial production of gems, and although the seductive character of such an investigation would no doubt appeal to many, it must be admitted that the geological laboratory is not and probably will never become the serious competitor of nature in those directions in which nature has produced her most brilliant effects.

In what has preceded I have laid emphasis upon the value of experimental measurements, in the systematic development of a more exact science of the earth. It is a fair question and one which is very often raised, whether all this investigation has a utilitarian side, whether the knowledge obtained in this way and with such difficulty, would help to solve any of the problems arising in the exploitation of our mineral resources or assist in our industrial development. It is neither wise nor expedient, in entering upon a new field of research, to expatiate long upon its practical utility. Its principles must first be established, after which there is no lack of ingenuity in finding profitable application of them.

The development of thermo-electric apparatus for the accurate measurement of high temperatures was begun and has been perfected in the interest of geophysical research, and it has already found such extended application among the technical industries as to demand the manufacture and calibration of thousands of such high-temperature thermometers every year. The tempering and impregnation of steel are no longer dependent upon the more or less trained eye of the workman, but are done at measured temperatures and under known conditions which guarantee the uniformity of the product and admit of adaptation to particular purposes, like high-speed tools or armor plate. This has the incidental but far-reaching industrial consequence that workmen of great individual skill in these industries are much less necessary now than formerly. Everything is accomplished by bringing temperature conditions under mechanical control and making them absolutely reproducible without the exercise of critical judgment.

A more intimate knowledge of the behavior of the minerals themselves finds almost immediate industrial application. An industry which has grown to enormous proportions in recent years is the manufacture of portland cement, about which little more has been known than that if certain natural minerals were taken in the proper proportions and heated in a peculiar furnace developed by experience, the resulting product could be mixed with water to form an artificial stone which has found extensive application in the building trades.

Chemical analysis readily established the fact that the chief ingredients in a successful portland cement were lime, alumina and silica, with a small admixture, perhaps, of iron and magnesia; but the relation in which these ingredients stood one to another—that is, which of them were necessary and which merely incidental—and in what compounds and what proportions the necessary ingredients required to be present, has never been satisfactorily established. When we know the stable compounds which lime, alumina and silica can combine to form, together with the conditions of equilibrium between these for different temperatures and percentages of each component, a formula can be written offhand for a successful portland cement from given ingredients somewhat in the same way as an experienced cook might write out the recipe for a successful dish.

Such definite and valuable knowledge is not within our reach. To obtain it requires, in fact, precisely the same system of procedure which has been described above and which has already been successfully applied to many of the natural minerals which have been reproduced and studied in the Geophysical Laboratory during the past five years.

It happens that we have examined a considerable number of these very mixtures in our recent work upon the rocks. All the compounds of lime, silica and alumina have been established, and a portion of the silica-magnesia series, and their relations have been definitely determined throughout the entire range of accessible temperatures. There is no reason to apprehend serious difficulty in applying the same procedure to the commercial ingredients of portland cement, and replacing the present rule-of-thumb methods and uncertain products with dependable cements. The problem of determining the relation of the ingredients in commercial cement and the conditions necessary for its successful formation is exactly the same in character as that of determining the conditions of formation of the rocks of the earth.

A physico-chemical investigation of the sulphide ores over a wide range of temperatures and pressures has also been undertaken, which has developed a large body of exact information of value in mining industry. And such illustrations could be continued almost indefinitely, if it would serve any useful purpose to do so.

The industrial world is not as a rule interested in scientific principles; the principle must first be narrowed down to the scope of the industrial requirement before its usefulness is apparent. The immediate effect of an industrial standpoint is, therefore, to restrict investigation at the risk of losing sight of underlying principles entirely.

An illustration of this has come down to us through the pages of history of a character to command and receive the utmost respect, for such another can hardly be expected to occur. We have honored the early philosophers for their splendid search after broad knowledge; but in what is now the field of chemistry they allowed themselves to be turned aside to the pursuit of a single, strictly utilitarian problem—the transmutation of base metals into gold. The history of chemistry is a history of this one problem from the fourth to the sixteenth century—twelve centuries before a man arose whose broader standpoint enabled him to divert the fruitless search into other channels from which a science has slowly arisen which is now so broad as to overlap most of the other sciences, and withal so practical that hardly an industry is entirely independent of it.

The so-called practical questions may therefore as well be left to take care of themselves. There has been no lack of ingenuity in making profitable application of systematic knowledge whenever the need for it became insistent, for the rewards of such effort are considerable. And it is no longer an argument against proceeding to establish relationships in a new field, that the scope of their application cannot be completely foreseen.

Now, what more promising questions occur to one than these: If the earth was originally fluid, as it appears to have been, and has gradually cooled down to its present state, its component minerals must at some time have been much more thoroughly mixed than now; how did they come to separate in the process of cooling into highly individualized masses and groups as we now find them, and what were the steps in their deposition? If the whole earth was hot, whence came the marble of which we have so much and which can withstand no heat? What has given us the valuable deposits of iron, of gold, of precious stones? What determines the various crystal forms found in the different minerals, and what is their relation? Some must have formed under pressure, some without pressure, some with the help of water, and some without. Where is the center, and what the source of energy in our volcanoes?

All these questions, and many more, the geophysicist may attempt to answer.

Geophysical Laboratory, Carnegie Institution.

Methods of Balancing Chemical Reaction Equations.

By F. B. Wilson.

The Summation Method.

The basic ideas involved in the summation method here detailed are, first, the resolution of any complex reaction into a series of more or less probable simple stages; second, the adjustment of the preliminary equations so as to eliminate any assumed intermediate substance; third, the summation of the adjusted equations to arrive at the final balanced form of the complete reaction equation.

To systematize the procedures, all reactions have been arranged in four groups so that all of the members of any one group may be resolved by the arbitrary scheme peculiar to that group. The following examples will illustrate these points.

Inspection of the statement of any reaction will show that it is possible to place it in some one of the following classes:

Class I.—All reactions involving the action of an acid or an alkaline hydroxide on a metal.

Class II.—All reactions involving the action of an acid or an alkaline hydroxide on a salt.

Class III.—All reactions in which the action of an oxidizing agent is an essential feature.

Class IV.—All reactions involving combinations of some of the preceding cases and also those reactions that cannot be referred to any of the preceding groups.

CLASS I.

Reactions Involving the Action of an Acid or an Alkaline Hydroxide on a Metal.

The method to be followed in handling members of this class involves the resolution of the reaction into a series of stages in such a way that the first preliminary equation will be one showing the action of the acid or alkaline hydroxide on the metal and the production of a salt and nascent hydrogen.

If the general statement shows that the products are a salt and hydrogen gas only, then the reaction is a simple one-stage reaction. But if a gas other than hydrogen is one of the observed products, then the nascent hydrogen produced in the first stage must be used in other reaction equations in such a manner as to give rise to the required products. The following cases will be worked out to show the application of this method to reactions of the first class.

Example 1.

$$aZn + bH_2SO_4 + aq = cZnSO_4 + dH + aq.$$

and

$$aZn + bKOH + aq. = cZn(OK)_2 + dH + aq.$$

From inspection of the statements it is evident that these are the simple cases in which the reaction is completed in one stage. The equations are balanced numerically by the adjustment of the quantity of hydrogen. The final forms are:

$$Zn + H_2SO_4 + aq = ZnSO_4 + H_2 + aq$$

and

$$Zn + 2\,KOH + aq. = Zn(OK)_2 + H_2 + aq.$$

Example 2.

$$aZn + bH_2SO_4 = cZnSO_4 + dSO_2 + eS + fH_2O.$$

Here a gas other than hydrogen is evolved, hence a second and third step will be required, showing how the action of the nascent hyydrogen on more molecules of acid gives rise to the SO_2, S and H_2O called for by the main statement. This is also a case where the use of the dualistic or oxide formulas will make the actions clearer.

(1) $H_2O{\cdot}SO_3 + Zn = ZnO{\cdot}SO_3 + (2\,H)$

(2) $H_2O{\cdot}SO_3 + 2\,H = SO_2 + H_2O$

(3) $H_2O{\cdot}SO_3 + 6\,H = S + 4\,H_2O$

Since all of the required products have been formed in these steps, no other steps are needed. So all that remains to be done is the adjustment that will permit the cancellation of the intermediate substance, active hydrogen. Eight atoms of hydrogen have been used, but two have been produced; therefore it will be necessary to repeat reaction (1) four times, or what amounts to the same thing, multiply all quantities in this equation by the factor four.

(1) $4\,H_2O{\cdot}SO_3 + 4\,Zn = 4\,ZnO{\cdot}SO_3 + (8\,H)$

The nascent hydrogen can then be eliminated on the basis of eight atoms and the sum of (2), (3) and (1′) will be the required balanced form.

$$6\,H_2SO_4 + 4\,Zn = 4\,ZnSO_4 + SO_2 + S + 6\,H_2O$$

CLASS II.

Reactions Involving the Action of an Acid or an Alkaline Hydroxide on a Salt.

The first step in the resolution of a second-class reaction is the writing of an equation showing the action of the acid or alkaline hydroxide on the salt and the production of another salt and a new hydrogen compound.

The products of this preliminary equation may be the required substances of the general statement, this, then, being a simple one-stage reaction, or one or both of these products may be converted into the new combinations required to satisfy the demands of the main statement.

Example 1.

$$aNaCl + bH_2SO_4 = cNaHSO_4 + dHCl.$$

This is a case so simple in character that the mere writing of the preliminary equation completes the work.

$$H_2SO_4 + NaCl = NaHSO_4 + HCl.$$

Example 2.

$$aNa_2S_2O_3 + bHCl + aq. = cNaCl + dSO_2 + eS + fH_2O + aq$$

The initial step is as follows:

(1) $2HCl + Na_2S_2O_3 = 2NaCl + (H_2S_2O_3).$

The resolution is then completed by writing the equation that shows the decomposition of the unstable thiosulfuric acid into the other substances required by the main statement. This will be:

(2) $(H_2S_2O_3) = H_2O + SO_2 + S.$

The $H_2S_2O_3$ is produced and decomposed in equivalent amounts in the equations as they stand, hence no adjustment is necessary previous to summing (1) and (2). The final form will be:

$$2HCl + Na_2S_2O_3 + aq. = 2NaCl + H_2O + SO_2 + S + aq.$$

Example 3.

$$aNH_4OH + bCuSO_4 + aq. = cCuSO_4(NH_3)_4 + dH_2O + aq.$$

Here, as in many other cases, it can be proved experimentally, by a suitable control of the conditions, that the reaction does actually proceed in two stages. The intermediate products, cupric hydroxide and ammonium sulphate, can be isolated as such. Therefore the regular preliminary equation represents a real and not an imaginary reaction.

(1) $2NH_4OH + CuSO_4 = [(NH_4)_2SO_4] + [Cu(OH)_2]$

Then the next step is:

(2) $[Cu(OH)_2] + [(NH_4)_2SO_4] + 2NH_4OH = CuSO_4(NH_3)_4 + 2H_2O.$

The sum of (1) and (2) is the required final form and thus we find:—

$$4\,NH_4OH + CuSO_4 + aq. = CuSO_4(NH_3)_4 + 4\,H_2O + aq$$

CLASS III.

Reactions in Which the Action of an Ordinary Oxidizing Agent is an Essential Feature.

The method used for third-class reactions employs, as the initial step, the resolution of the oxidizing agent into a number of simple oxides and the consequent amount of available or active oxygen.

The various oxides and the active oxygen are then used to bring about the results required by the general statement of the given reaction.

Example 1.

$$aFeSO_4 + bH_2SO_4 + cHNO_3 + aq. = dFe_2(SO_4)_3 + eNO + fH_2O + aq.$$

Proceeding in the manner mentioned and using the dualistic formula for the oxidizing agent, the various steps will be:

(1) $H_2O{\cdot}N_2O_5 = H_2O + 2\,NO + (3\,O)$

(2) $H_2SO_4 + (O) = H_2O + (SO_4)$

(3) $2\,FeSO_4 + (SO_4) = Fe_2(SO_4)_3$

Now the second and third equations must each be multiplied throughout by three in order to use the total amount of available oxygen and thus make it possible to eliminate it together with the other intermediate substance, (SO_4). These steps will then become:

(2′) $3\,H_2SO + (3\,O) = 3\,H_2O + (3\,SO_4)$

(3′) $6\,FeSO_4 + (3\,SO_4) = 3\,Fe_2(SO_4)_3$

The sum of (1), (2′) and (3′) will be the desired form.

$$6\,FeSO_4 + 3\,H_2SO_4 + 2\,HNO_3 + aq. = 3\,Fe_2(SO_4)_3 + 2\,NO + 4\,H_2O + aq.$$

Example 2.

$$aKMnO_4 + bNa_2C_2O_4 + cH_2SO_4 + aq. = dK_2SO_4 + eNa_2SO_4 + fMnSO_4 + gH_2O + hCO_2 + aq$$

The oxidizing agent is decomposed into the oxides that are needed to make the final products and the residual amount of active oxygen.

(1) $K_2O\,Mn_2O_7 = (K_2O) + (2\,MnO) + (5\,O)$

Then the oxidizable substance is resolved in such a manner as to show what portion is to use the available oxygen of the preceding step.

(2) $Na_2C_2O_4 = (Na_2O) + CO_2 + (CO)$

The other steps will be:

(3) $(CO) + (O) = CO_2$

(4) $(K_2O) + H_2SO_4 = K_2SO_4 + H_2O$

(5) $(Na_2O) + H_2SO_4 = Na_2SO_4 + H_2O$

and

(6) $(MnO) + H_2SO_4 = MnSO_4 + H_2O$

These equations must be adjusted so as to permit the cancellation of equivalent quantities of the intermediate substances. The complete series, when adjusted, will be:

(1) $K_2O\,Mn_2O_7 = (K_2O) + (2\,MnO) + 5\,O$

(2′) $5\,Na_2C_2O_4 = (5\,Na_2O) + 5\,CO_2 + (5\,CO)$

(3′) $(5\,CO) + (5\,O) = 5\,CO_2$

(4) $(K_2O) + H_2SO_4 = K_2SO_4 + H_2O$

(5′) $(5\,Na_2O) + 5\,H_2SO_4 = 5\,Na_2SO_4 + 5\,H_2O$

(6′) $(2\,MnO) + 2\,H_2SO_4 = 2\,MnSO_4 + 2\,H_2O$

The sum of these equations will give the final balanced form.

$$2\,KMnO_4 + 5\,Na_2C_2O_4 + 8\,H_2SO_4 + aq. = K_2SO_4 + 5\,Na_2SO_4 + 2\,MnSO_4 + 8\,H_2O + 10\,CO_2 + aq.$$

CLASS IV.

Reactions Involving Combinations of Some of the Preceding Cases and Also Those Reactions That Cannot be Referred to Any of the Preceding Groups.

The methods used for fourth-class reactions will be combinations of the schemes employed in those classes to which the given compound reaction may be referred; or else they will be special methods that must be developed for those cases that cannot be referred to any of the preceding classes.

Example 1.

$$aKCl + bH_2SO_4 + cMnO_2 = dKHSO_4 + eCl + fH_2O + gMnSO_4.$$

This case is obviously a combination of a second and third-class reaction. And a combination of second and third-class procedures will give the desired result.

(1) $H_2SO_4 + KCl = KHSO_4 + (HCl)$

(2) $MnO_2 = (MnO) + (O)$

(3) $(MnO) + H_2SO_4 = MnSO_4 + H_2O$

(4) $(2\,HCl) + (O) = 2\,Cl + H_2O$

(1′) $2\,H_2SO_4 + 2\,KCl = 2\,KHSO_4 + (2\,HCl)$

Then the sum of (2), (3), (4) and (1′) is the final balanced form.

$$3\,H_2SO_4 + 2\,KCl + MnO_2 = 2\,KHSO_4 + MnSO_4 + 2\,Cl + 2\,H_2O.$$

Example 2.

$$aKOH + bCl + aq. = cKClO_3 + dKCl + eH_2O + aq.$$

This is the typical fourth-class reaction requiring the development of a special procedure for its resolution. Potassium hypochlorite, KClO, will be taken as the intermediate product, since such a compound can actually be formed by a suitable control of the conditions.

(1) $2\,KOH + 2\,Cl = KCl + (KClO) + H_2O$

(2) $(3\,KClO) = KClO_3 + 2\,KCl$

(1′) $6\,KOH + 6\,Cl = 3\,KCl + (3\,KClO) + 3\,H_2O$

The sum of (2) and (1′) will be the final balanced form,

$$6\,KOH + 6\,Cl + aq. = KClO_3 + 5\,KCl + 3\,H_2O + aq.$$

Other Methods.

Another method that may be used for balancing equations is the one devised by Prof. O. C. Johnson and which is fully explained in the sixth edition of Prescott and Johnson's Qualitative Chemical Analysis on page 238.

Still another method that may be used in many cases is the algebraic method. The procedures will be illustrated by an example.

Example 1.

$$aHNO_3 + bCu + aq. = cCu(NO_3)_2 + dNO + eH_2O + aq.$$

This statement involves four different kinds of elements and five unknown coefficients. Still it is possible to arrange a series of independent algebraic equations and obtain values for the coefficients. On the basis of the different elements present the following equations can be written:

(H) $a = 2e$

(N) $a = 2c + d$

(O) $3a = 6c + d + e$

(Cu) $b = c$

Then by suitable transformations, values for each unknown in terms of some particular one can be evolved. The following are the secondary equations in terms of c:

$$a = 8/3\,c,\ b = c,\ c = c,\ d = 2/3\,c,\ e = 4/3\,c.$$

Then, by making $c = 3$, to eliminate fractional values, the coefficients for the reaction equation will be: $a = 8$; $b = 3$; $c = 3$; $d = 2$ and $e = 4$. The final form will be:

$$8\,HNO_3 + 3\,Cu + aq. = 3\,Cu(NO_3)_2 + 2\,NO + 4\,H_2O + aq$$

A Method for Measuring the Compressive Strength of Alloys

By J. R. Hobbs.

The resistance of alloys to compression and methods for determining this important property are subjects which are conspicuous by their absence from the columns of our scientific literature. This is largely due to the fact that the different alloys vary widely in their behavior under compression. Some of them will break before showing any distortion, others will bulge or bend before breaking, and still others, like lead, will flatten out into a thin sheet and show no tendency to rupture. Owing to this variation it is exceedingly difficult to adopt a unit of measurement and a standard shape of test specimen which would be applicable in all cases.

The situation is very well summed up by Kent as follows: "For future experiments on crushing strength three things are desirable: First, an arbitrary standard shape and size of test specimen for comparison of all materials. Secondly, a standard limit of compression for ductile materials which shall be considered equivalent to fracture in brittle materials. Thirdly, an accurate knowledge of the relation of the crushing strength of a specimen of standard shape and size to the crushing strength of specimens of all other shapes and sizes. The latter can only be secured by a very extensive and accurate series of experiments upon all kinds of materials, and on specimens of a great number of different shapes and sizes."

The following method was worked out in this laboratory in connection with some research work on the white metal alloys, and proved very satisfactory. A cylindrical test piece was adopted owing to the ease with which it could be accurately machined in a lathe, as compared with the difficulty and expense of machining an accurate cube. The test pieces were 1 in. long and 1.128 in. in diameter, giving a cross-section having an area of 1 sq. in. A 50,000-lb. latest type, Olsen testing machine was used. The micrometer head was a 1-in. Brown & Sharpe, graduated to ten thousandths. The end of the micrometer head holder was threaded to fit the upper test bar holder of the machine. The lower one was removed and the 1 by 6-in. iron disk, which is supplied with the machine, was fastened in its place. The top of the bolt which holds this disk was rounded off to form a smooth spot upon which to screw the micrometer down. The cylindrical test piece was placed between two hardened steel disks 1-in. thick and 4 in. in diameter, which were obtained for the purpose. These were placed in the center of the base of the machine and the table lowered until the iron disk pressed upon the upper steel disk.

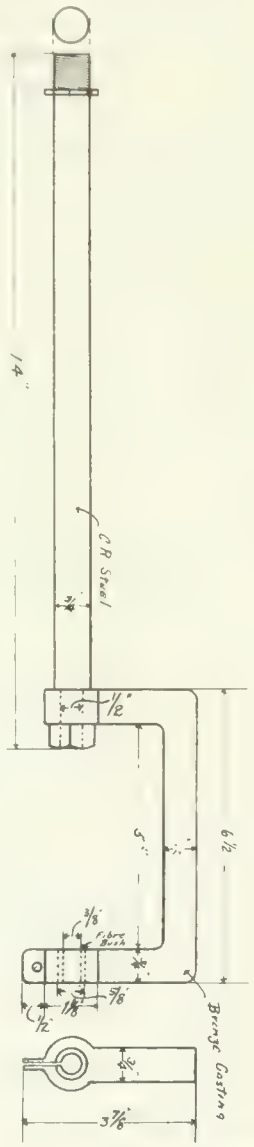

FIG. 1. — MICROMETER HEAD HOLDER.

In making the test an initial load of about 200 lb. was applied to accurately seat the specimen. The machine was turned backward by hand very carefully until the beam just balanced. The micrometer was then screwed down by means of the ratchet top and a zero reading taken. In the case of the softer alloys and where only the lower end of the curve was explored the machine was turned by hand throughout the test. The load was applied in increments of 200 lb. and a reading taken after each additional load.

With the harder alloys, where larger increments were applied and the whole capacity of the machine used, it was found practicable to run the machine with power and use the slowest speed.

FIG. 2. — APPARATUS FOR MEASURING COMPRESSION STRENGTH OF ALLOYS.

The curves obtained from these tests indicated the behavior of the specimen under a steadily applied and increasing load, but the permanent set at each point was not obtained. This would probably vary with the elasticity of the alloy.

Although this method is not offered as a solution of the problem of compressive strength measurements it gave some very accurate comparative data on a series of non-ferrous alloys.

Lumen Bearing Co., Buffalo, N. Y.

The Wislicenus Smokestack for Fume Dilution was described in our December, 1911, issue (Vol. IX, p. 606), the essential feature being the construction of the upper part of the stack in lattice form. The American rights have been acquired by the Metallurgical Company of America, 52 Broadway, New York.

Shortage of water is a serious hindrance to good concentration work, and frequently means must be adopted to conserve the tailing water. The Frontenac mill, Black Hawk, Col., has recently added to its equipment a series of settling tanks for this purpose. The tailings from all machines are elevated to the settler, which consists of a series of boxes with hopper bottoms sloping to a central discharge spigot. The spigots are adjusted to allow thickened tailing to run to waste, while the water overflows from one box to the next, traveling 60 ft. before being drawn back to the mill system. This arrangement is expected to overcome the difficulties arising from muddy creek water, which, at certain times of the year, is insufficient for the demands of the mill.

Alunite is a newly discovered source of potash in the United States The largest occurrence is near Marysvale, Utah, and the deposit is of such importance that the U. S. Geological Survey has just issued a special *Bulletin*, No. 511, dealing with this particular deposit, and with alunite in general.

The Thermal Insulation of Furnace Walls.

BY CARL HERING.

The loss of heat through the walls of electric furnaces is of considerable importance because the heat is generally much more expensive than fuel heat and because these losses are by no means small. In cases in which the material is merely kept at a constant temperature, like in steel refining, this loss through the walls may even constitute the major part, and in fact sometimes nearly the entire input of power required. Moreover, often it is the cost of the power which is the criterion as to whether or not an electric furnace is to be adopted.

It is, therefore, often of importance for the engineer to be able to predetermine the best wall dimensions by calculating the loss for each of various alternative designs. Such calculations of the flow of heat through bodies, and deductions from them are perhaps not made as freely and as often as they should be, partly probably because they are considered to be tedious, and partly because they may not be generally understood. When properly made, however, they are in fact so exceedingly simple that there is no good reason for not making them when necessary in working out designs and estimates. The main point lies in the proper choice of those units which will reduce the calculations to the simplest possible; it, therefore, involves a problem in what might be called the conservation of mental effort. The units generally used make the calculation far more tedious than they need be.

The writer has from time to time published articles, papers, and discussions pertaining to various phases of this subject; the object of the present article is to summarize briefly the salient features and conclusions in these scattered publications, combining them into a brief description of how, in the writer's opinion, such calculations had best be made, how the results are to be interpreted, and what the chief factors are which govern such insulation.

Thermal and Electric Currents.—A flow of heat through a body may in many respects be treated just like a flow of electricity, known as an electric current. It is always caused by a difference of temperature, just as an electric current is always due to a difference of potential; where no such difference exists there will be no flow. The greater the difference of temperature the greater the flow (other things remaining the same). Such a flow is opposed by a thermal resistance; the greater this resistance the less the flow.

Stable State.—A flow of heat differs from one of electricity in that it is slow, while the latter is practically instantaneous; hence thermal calculations generally refer to the so-called steady or stable state when the flow of heat has become constant, which means that every part of the conductor has acquired the highest temperature to which it will be raised by the flowing heat under the normal conditions of a continuous and steady flow, and that the flow has reached its minimum; in this way the slower speed of the flow of heat may be eliminated from consideration.

The importance of fully appreciating the significance of this stable state may be shown by a case in which the inside layer of a furnace wall is a good heat conductor, like magnesite brick, while the outside is made of a very good insulator like mineral wool. In such a case, when this stable state has been reached it follows that the temperature at the junction of the two layers will be nearly that of the interior of the furnace, and such a high temperature may destroy the mineral wool. The higher the insulation of the outside layer the higher will be the temperature at this junction. When this stable state has been reached, the heat flowing from the hot charge has reached its minimum. It is like filling a thick, dry, porous cup with water; at first a large amount of water is absorbed by the walls of the cup, then it becomes less and less until a stable state of flow through the walls is reached.

Over Insulation.—With very high outside insulation it may happen that the temperature of the inside layer becomes higher than it can stand without softening, thereby collapsing, as for instance in the case of an arched roof. Such a case may be termed over insulation, and this has no doubt often been the cause of failure of inner parts of walls. For exceedingly high temperatures, as, for instance, in arc furnaces, it may therefore be absolutely necessary to permit a considerable flow in order to reduce the temperature of the bricks sufficiently, for wherever there is a flow there must be a lowering of the temperature.

No Perfect Insulator.—A thermal flow also differs from a flow of electricity in that such a thing as a practically perfect heat insulator does not exist; a vacuum is an exception, but as its use is impractical except for Dewar flasks, known popularly as thermos bottles, or in the laboratory, it may here be neglected; moreover, it is no insulator of radiant heat, as we get such heat from the sun through a vacuum; but with this we are not now concerned, as we are considering only the conduction of heat through walls. The absence of anything even approaching a perfect heat insulator means that some heat will always flow and that it cannot be confined to a conductor but will flow in any and all directions where lower temperatures exist.

Virtually Perfect Insulation.—The only way known to keep heat from flowing out through the sides of a conductor, that is, to compel it to flow in at one end of a conductor and out at the other, is to surround that conductor with a material which at each point has the same temperature as that of the adjacent point of the conductor. This is approximately the case with every cone-shaped, radial element into which a furnace wall may be assumed to be divided; in such elements the flow may therefore be assumed to be constant (in amount, not in density) through every cross section, like a cone-shaped electrical conductor; hence the quantity of heat which flows out of the cold end is equal to that which enters the hot end (assuming, of course, that the stable state has been reached); this is assumed to be the case in all that follows.

Units; Watts.—In calculations of electrical furnaces by far the simplest and most rational unit of flow of heat is the watt; this is also easily reduced to the kilowatt. The writer pointed out some years ago that this was a strictly correct measure of a thermal flow. Hence the older unit, calories (large and small) and thermal units per second, should be abandoned in electric furnace calculations. It is best to reduce all the necessary physical constants in tables once for all to watts. Gram calories per second $\times$ 4.18617 = watts; and watts $\times$ 0.238882 = gram calories per second. For further reduction factors see the writer's Conversion Tables.

Centigrade Scale.—The best temperature unit is, of course, the centigrade degree; partly because tables and data in all the best modern, up-to-date books are in that unit, and partly because it is the duty of every progressive engineer to do what he can to rid our calculations of such an irrational, awkward, senseless and cumbersome measure as the Fahrenheit scale. Moreover, in heat flow calculations the temperature difference should be stated as one number (just as in electrical calculations a potential difference is always stated as a voltage), not in the awkward and clumsy form "T-t" so common in the older text books. The highest of these two temperatures is always given elsewhere in a problem, hence is known. To reduce a drop of temperature in Fahrenheit degrees (not the temperature reading itself) to the drop in centigrade degrees, multiply by 5/9.

Resistance, not Conductance.—For furnace wall calculations, the successive layers of insulation are in series, hence it is far simpler[1] to use thermal resistances and resistivities (specific resistances) instead of conductances and conductivities (specific conductances) as usually used in the older text books. This will save an immense amount of tedious calcula-

[1] This journal, Vol. VII., 1909, p. 11.

tions with reciprocals. It also enables the temperature at the junctions of different layers to be readily determined. Moreover, like in electrical calculations, it is often much simpler to calculate resistances by themselves as such and not always have to calculate the heat flow also, as was formerly customary.

Thermal Ohm.—By far the simplest unit to use for thermal resistances, is a new one suggested by the writer, and not yet found in text books; the name given it is the thermal ohm.[1] The reason for using this new unit is that it greatly reduces and simplifies calculations, the unit being chosen to eliminate troublesome numerical coefficients or conversion factors, as will be shown below. It is also hoped that it will lead to uniformity in stating such data hereafter.

A thermal ohm is that thermal resistance through which 1 watt will flow when the difference in temperature is 1° C.

Tables of physical constants in text books usually give this physical property in terms of a thermal conductivity, instead of a resistivity, and often in terms of calories per second, though sometimes also in B.t.u., there being altogether about six or eight different units in use. The electric furnace engineer will find it greatly to his advantage to reduce all such data once for all to thermal ohms, thereby saving himself many subsequent tedious calculations; such a table was published in the December issue of this journal, p. 653. "Calories per second" and "B.t.u. per hour, minute or second" are thereby completely eliminated from all his calculations.

To reduce thermal conductivities given in terms of gram calories per second for 1° C. and a centimeter or inch cube, to specific resistances in thermal ohms, multiply the reciprocal of that number by 0.238882. Thus the thermal conductivity of fine grained quartz sand is given in the tables as 0.000131, meaning that so many gram calories of heat will flow through each square centimeter of a plate 1 cm thick, when the difference of temperature between the two faces is 1° C. The thermal resistivity will therefore be $0.2389 \times 1/0.000131 = 1820$. thermal ohms, for a centimeter cube. To reduce this to 1-in. cube multiply by 0.3937 or use 0.0940478 instead of 0.238882 in the first reduction. To reduce conductivity units in B.t.u. (pound-Fahr. units) per hour, per square foot, per inch thickness, per degree Fahrenheit, to thermal ohms, inch cube units, multiply the reciprocal by 273.013. For further conversion factors see the article on the thermal ohm cited above, and the writer's Conversion Tables.

The resistivity of the metals vary from about 0.25 to about 3 in thermal ohms for one centimeter cube; various furnace bricks from about 10 to 150; granular or fibrous materials, about 250 to 6000. The unit is therefore a convenient one to use in practice. It is, moreover, equal to 10^{-7} times the true absolute unit (not the so-called absolute unit based on the gram calorie), hence is a rational unit and is in decimal relation with the electrical units.

Thermal Ohm's Law.—When the above units are used, the calculation of flows of heat become the acme of simplicity; the law is then the exact duplicate of the electrician's favorite Ohm's law. If W is the flow of heat in watts, T the temperature drop in Centigrade degrees and R the thermal resistance in thermal ohms, then $W = T/R$. Therefore by using the thermal ohm all further reduction factors or coefficients disappear by becoming unity like in Ohm's law.

If, for instance, the drop of temperature between the inside and outside of a wall of an electric furnace is 1500° C. and the total resistance is 0.05 thermal ohms, the loss will be $1500/0.05 = 30$ kw. Or if the allowable loss is 30 kw the insulation resistance must be $1500/30{,}000 = 0.05$ thermal ohms.

Thermal Resistance of a Body.—The total thermal resistance of a given body, like a furnace wall or any part of it, is determined just like in electrical calculations. If r is the thermal resistivity (specific resistance) of the material in thermal ohms (obtained from tables), then the total resistance R of the particular body, in thermal ohms, is $R = rL/S$, in which L is the length and S the cross section. This, of course, applies equally well to inches as to centimeters, provided the same units are used consistently throughout. The thermal ohm as a unit is, of course, independent of any units of length or section; but with specific resistances (resistivities) one must specify whether they refer to the centimeter cube or the inch cube.

If, for instance, the mean thermal resistivity of fire brick is 30 thermal ohms in cu. in. units, then the resistance of a brick 8 x 4 x 2 in., taken between its two flat sides, will be $R = 30 \times 2/32 = 1.87$ thermal ohms.

Several Layers.—When a wall consists of several layers of different materials, the resistance of each layer is first calculated by itself, and as they are in series, they are then added to give the total resistance; from this total the flow is then calculated when the inside and outside temperatures are known. It would, of course, be incorrect to calculate the flow in each one separately, as the temperature drops in each are not a matter of choice, but are a consequence. However, if one wishes to arbitrarily fix the temperature at the junction of different layers, one can then determine what the resistance must be in order to produce that drop in each case, on the basis of an assumed flow. From this resistance one can then calculate what the length and section must be to give this amount of insulation resistance.

As an example, taking simple figures and omitting joints, mortar, etc., let it be decided to have a 4-in. layer of magnesite brick in the inside, then a layer of 12 in. of fire brick, and finally ¼ in. of sand between the brick and the casing; total 16¼ in. Assume the resistivity of the magnesite brick in thermal ohms to be 14 in inch units, fire brick 29, and sand 109 (the writer assumes no responsibility for these data, but they are probably approximately correct). In order to make the problem more general, assume a radial piece of the wall 1 sq. ft. in section at the inside wall surface, and for simplicity neglect the flare.

The resistance of the layer of magnesite brick then is $14 \times 4/144 = 0.39$ thermal ohm; of the fire brick $29 \times 12/144 = 2.42$; of the sand $109 \times .25/144 = 0.19$; total 3.0 thermal ohms. If the drop of temperature was then found in an actual case to be 1500° C., the loss through a square foot equals 1500°/3 thermal ohms = 500 watts.

In this class of problems either the drop of temperature or the loss in watts must be known or assumed in order to determine the other.

Suppose the thickness of the outside layer of sand was left to be determined so that the outside temperature should not exceed 100°, when it is 1600° inside; and on the basis of an allowable loss of 500 watts per square foot of inner surface. The total resistance must be $1500/500 = 3$ thermal ohms; that of the magnesia and fire brick together is 2.81, leaving .19 to be supplied by the sand. The thickness is then found from the resistance formula to be $0.19 \times 144./109. = 0.25$ in.

Suppose as an alternative the fire brick be reduced by one course, hence is only 8 in., and that this course be replaced by 4 in. of sand on the outside; total 16 in. Then the resistances will be 0.39, 1.06 and 3.03, total 4.48 thermal ohms, which with the same drop of temperature 1500° gives 335 watts; hence with a slightly thinner wall and a cheaper material the loss is considerably less than before.

Temperatures at the Joints.—With the same simple formula the temperatures at the joints of such layers can readily be calculated if the inside temperature and the total drop are known. It may sometimes be necessary to calculate these temperatures in order to find whether the materials of each layer can stand them. In the first of the above examples the drop in the magnesite brick will be $T = WR = 500 \times 0.39 = 195°$. Hence if the inside temperature is 1600° that at the first joint

[1] Journal, Vol. IX, January, [illegible] Am. Inst. Elec. Engrs., 1911, p. 66.

will be 1000 — 105 = 1405° C. The questions of whether the fire brick will stand this or whether it will flux with the magnesite and run off, whether the magnesite will soften all the way back to its cooler side, hence lose its strength, etc., must then be considered. The drop through the fire brick will, by a similar calculation, be $500 \times 2.46 = 1230°$, hence the temperature at the sand is $1405 - 1230 = 175°$. The drop through the sand is 95°. Adding all these drops gives the total, 1500°, as nearly as can be expected from such abbreviated figures.

In the second example, with the thicker layer of sand, it will in this way be found that the fire brick junction with the magnesite is still higher, 1470°, because the heat flow is considerably less. Also that the hot side of the sand layer will now be 1120° C, the drop through the 4 inches of sand being now very great, namely 1010°. Knowing these temperatures the calculations should then be repeated with the resistivities for those temperatures.

Using conductivities as recommended in most text books instead of resistivities these extremely simply calculations would become very tedious; and using any other unit than the thermal ohm, they would be burdened with the incessant use of conversion factors besides considerably more mental effort in order not to make errors.

Flare of Walls.—The wall thickness in a well-insulated furnace being thick relatively to the inside, especially in smaller furnaces, it becomes necessary to consider the flare, as the outside layers have not the same insulating effect per inch of thickness on account of their larger cross-section perpendicular to the flow.

The rough-and-ready rule to take the simple arithmetic mean of the two end surfaces is only approximately correct and only when the flare is small; for relatively great flares, such as may exist in smaller furnaces, the error becomes quite great, and beyond a certain range, namely, at a thickness equal to about three-fourths the inside dimensions, it leads to the absurdity that the loss becomes greater with thicker walls. Hence it should not be used except for thin layers in which the flare is small.

For a spherical or a cubical furnace or any parts of the same, like one-half, the correct mean value is the square root of the product of the two surfaces, that is, their geometric mean. For other shapes approaching these this mean cannot be far wrong. For cylindrical furnaces the correct law is not so simple as it involves logarithmic functions, but as cylindrical furnaces are generally short and necessarily have large ends, it would probably be correct within the errors of other parts of the calculations to use the geometric mean in such a case also.

In some recent papers* the writer gave the rigidly correct formulas, and by applying them showed how rapidly the insulation value of the outer layers decreased as the thickness increased owing to this flare.

The curves in Fig. 1 are reproduced from one of these papers, but are here reduced to watts, thermal ohms and centigrade degrees; they are for spherical and cubical shapes, as these are the only two for which a single curve can be given for all sizes; for shapes approximating these the results would probably not be far wrong.

The vertical distances, after certain reductions, give the losses in watts per centigrade degree of drop in temperature when the horizontal distances represent the relative wall thicknesses. It will be seen how very rapidly the losses decrease at first for relatively thin walls, but as the thickness increases considerably the rate of decrease of the loss becomes quite slow, and as the volume of the insulation material per extra inch of thickness then increases quite rapidly, namely, as the square of the distance from the center, it becomes questionable whether the extra saving of the loss is justified by the expense. For reasonably thick walls it may be truly said that "bricks are cheaper than kilowatts," but a practical limit is reached, especially for tilting furnaces in which the additional size and weight become objectionable.

The curves are here drawn to scale so that the losses may be determined from them directly in watts thereby saving the tedious calculations of the geometric means. They are drawn

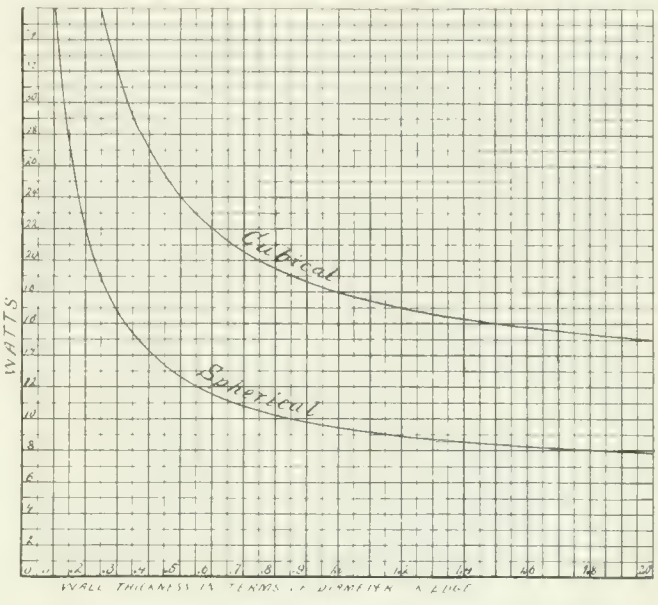

FIG. 1. LOSSES IN CUBICAL AND SPHERICAL FURNACES.

for 1 inch or centimeter inside diameter of a sphere or the edge of a cube, and for a resistivity of one thermal ohm in inches or centimeters respectively. The horizontal distances give the wall thickness in terms of the diameter or edge; for instance, 1.2 on that scale means that the wall thickness is 1.2 times the inside diameter or edge, in either inches or centimeters. Hence by merely multiplying the watts given by these curves by the actual diameter in inches or centimeters and dividing by the actual resistivity in thermal ohms, in either inches or centimeters, the result will be the total loss for the whole furnace per degree drop of temperature. This need then merely be multiplied by the total temperature drop to get the total loss in watts.

For instance, if the inside diameter of a spherical furnace is 20 inches and the wall thickness 24 inches, then the thickness is 1.2 times the diameter; for 1.2 on the lower scale the watts are 8.9. Let the walls be of fire brick having a resistivity of, say, 30. Then $8.9 \times 20/30 = 5.93$ watts per degree, hence, for 1000° it will be 5.93 kilowatts.

This assumes that the whole of the inside surface is at the same temperature, hence that the heat is supplied to the inner surface as fast as it flows away. This is probably approximately true when the loss is relatively small per unit of surface, but when rather great there will probably be less heat loss per unit area above the level of the molten charge in a resistance furnace in which the heat is generated in the material, and more in this upper part than in the lower in arc and reverberatory furnaces in which the space above the charge is the hotter as the heat is generated there.

Under the assumption of uniform temperature over the inside surface, the following can be shown to be true for spherical or cubical furnaces, which are the only definite shapes for which such general rigidly correct laws can be made. It is also assumed herein that the resistivity of the materials is uniform throughout, which is not strictly correct, but some such assumptions of uniformity must be made or else no general laws could be established, and such laws are often valuable guides

*Heat Conductances Through Walls of Furnaces. Hering, Trans. Amer. Electrochem. Soc., Vol. 14, 1908, p. 215. For a more detailed discussion of the correct formula for long cylinders see "Thickness of Electric and Thermal Insulation," Elec. World, Nov. 25, p. 1303.

For the *same actual loss* in furnaces of different inside dimensions, the wall thickness increases with very great rapidity as the inside size increases, in fact far too rapidly to make it practicable to maintain the loss the same for the larger furnaces. For instance, for four times the inner diameter the volume of insulation is about 2500 times as great. This does not mean that furnaces should not be made large, but merely that it is of very great importance not to make the inside dimension any larger than necessary to hold the charge. This applies more particularly to the hottest part, which is below the liquid level in resistance furnaces, and above it in arc furnaces.

For the *same relative loss*, that is, for the same per cent loss or the same loss per unit inside volume or pound of charge, just the reverse is true, that is, the thickness becomes impracticably great for the smaller sizes and relatively very small, becoming nearly constant for the larger ones. The volume of insulation in this case is even far greater for the smaller sizes. This shows the futility of trying to insulate a small furnace as well as a large one, except when a very large bulk is not objectionable, as in some laboratory furnaces. It also shows the great advantage of furnaces of large capacity over those for smaller ones, also the great importance of using one large furnace instead of several smaller ones, unless there are other considerations of more importance than these losses.

For the *same relative thickness* of wall the loss in spherical furnaces increases as the diameter. But the contents increase as the cube of the diameter, hence the loss per pound of charge decreases rapidly with increasing sizes.

Comparing a sphere with a cube whose edge is equal to the diameter of the sphere, both having the same wall thicknesses, the loss per unit of volume is the same; the cube, however, will have nearly twice the capacity. For the same capacity and the same relative wall thickness, the loss for the spherical one will be considerably less.

For cubical furnaces with the same relative wall thickness, the losses are proportional to the length of the edge, like with the spherical one.

All the above apply, of course, also to any fraction of a sphere or cube, like a half or to one of the sides of a cube.

For oblong, rectangular furnaces it will probably be sufficiently accurate to use the geometric mean of the inside and outside surfaces as the mean section.

For cylinders the losses are the same for all diameters when the relative thicknesses remain the same, but this applies only to long cylinders and does not include the ends, hence would not apply to short cylindrical electric furnaces.

If the inside diameter of a spherical furnace is d, the outside D and the thickness L, all in inches or centimeters, and if the resistivity is r in thermal ohms, then the total resistance in thermal ohms can be calculated from the formula $R = rL/(\pi Dd)$ which avoids the tedious square root calculation for obtaining the geometric mean, yet is rigidly correct.*

Similarly for a cube whose inside edge is d, the outside one D and the thickness L, the resistance $R = rL/(6Dd)$.

These modified formulas also show the general law that the resistance, hence the loss, will be the same in all different spherical furnaces when the product of the two diameters divided by their difference (namely, twice the wall thickness) is the same. This is true also of cubical furnaces in which the edges take the place of the diameters.

These formulas apply to the whole wall; for a hemisphere one-half is taken, and for one face of a cube one-sixth.

For further details concerning flaring walls see the original article cited above, from which this is taken.

Temperature Coefficient.—Little seems to be known about the temperature coefficients of the thermal resistances of insulators, but for high temperatures, such as in furnaces, even a small temperature coefficient makes quite an appreciable difference, and should therefore not be neglected. As a rule, the thermal resistance of heat insulators seems to become less as the temperature increases. The constants as usually given for low temperatures are therefore not reliable to use for high ones without some allowance. In tables these constants should therefore always be accompanied by the temperatures at which they were determined.

Nusselt,* who determined apparently very good values of the thermal conductivities of a number of thermal insulators (though, unfortunately, not of those usually used for the walls of high temperature furnaces), states that approximately the conductivity of such insulators increases 1/273 of their value for each centigrade degree from 0°C.; this is approximately the same rate (though of different sign) as for the electrical resistivity of copper. If this law continues for high temperatures, then at 273° C. above 0° the conductance of a body would be doubled or the resistance halved; at about 1100° C. the resistance would be only one-fourth, and at about 1350° only one-fifth that at ordinary temperature. The importance of taking this into consideration is therefore evident.

When the mean resistivity of a material is given for both a small and a large range of temperature both from zero, or room temperatures, say from 0° to 500° and again from 0° to 1300°, it is possible to calculate definitely what the mean value will be between the two higher temperatures, from 500° to 1300° in this case, and without the assumption of any law of variation.** If t is the drop of temperature (hence not necessarily the temperature itself) for the small range, T that for the larger range, D the drop between the two high temperatures, for which the mean resistivity is desired (hence $1300 - 500 = 800°$ in this case); and if r is the mean resistivity for the smaller range, R for the larger one, and X for the high range D then

$$X = \frac{rRD}{rT - Rt}$$

It is correct for any units provided they are used consistently throughout.

Air Spaces Within Walls.—Ray and Kreisinger*** recently showed that an air space left between the two parts of a double wall for insulation purposes did not accomplish its object, as the effective resistance of this air space was less than if it had been filled with bricks.

A deduction made by the writer,† which would follow from the laws used by them, is that increasing such an air space would actually decrease the total resistance. The reason apparently is that on account of the greater air space the outside wall becomes larger, hence conducts better.

Joints.—Little seems to be known quantitatively about the resistance of a joint between two bricks, but it is known that with good conductors of heat like the metals even a very thin crack affords such a great resistance that the metal may be red hot on one side of it, while it is black on the other. It is likely therefore that the same thing is true, though possibly to a less extent, with heat insulators. Hence where bricks are not cemented together with mortar to form practically one solid mass, the joints are likely to offer very appreciable insulation resistances, and if so, they are the cheapest kind of insulation, involving also no weight or space. The writer recently constructed a furnace in which the bricks were all laid parallel to the outer sides, thus making as many joints as possible perpendicular to the flow and the iron casing on the outside of this furnace became only slightly warm to the touch. Most of the bricks were of a particularly porous kind and very light in weight.

*This formula is a good illustration of how an equation, which has not been reduced to its simplest terms (as L is half of Dd, hence could be eliminated) is really simpler to use arithmetically than the reduced form.

*Nusselt. Zeit. Ver. Duet. Eng., June, 1908, p. 906.

**This journal, Feb., 1909, p. 72, where the formula is deduced for conductivities instead of resistivities.

***Bureau of Mines, Bulletin No. 8.

†This journal, Sept., 1911, p. 438.

Actual Losses Through Walls.—The writer found that the leakage of heat through the walls of two presumably well-built commercial furnaces was roughly about 1 kw. per square foot of surface of the molten charge, assuming this rate to be about the same from the top surfaces as through the walls. This figure was obtained from experimental data of two induction furnaces of entirely different sizes and manufacture* by measuring the input of energy over night while the furnaces were merely kept hot (presumably above the melting temperature of steel) which input, therefore, represented the continuous losses. The figures for the two different furnaces agreed remarkably closely, which was in part no doubt accidental. The individual figures were both a little higher, and presumably at the working temperatures the loss would be somewhat higher still. But, on the other hand, in a furnace which is not restricted in its insulation in both thickness and rigidity, as an induction furnace necessarily is, the insulation could no doubt be improved so as to reduce this figure, and for this reason it is believed that 1 kw. per square foot is a safe rough-and-ready figure to use.

This will give a good general idea of the magnitude of these thermal leakages through walls. If published figures of the thermal conductivities of various refractory bricks are correct, and if numerous joints can be introduced as in the brick work of the usual furnaces, it would seem to be possible to reduce this possibly to a half or even less. It should, therefore, be used merely as a very crude figure.

Shape.—It is evident that the loss of heat from a charge must all take place through the sides, bottom and top of the charge, that is, through its bounding surfaces. Hence it would be reduced to a minimum when the charge is in the shape of a sphere, which has the least surface for a given volume. As this is impracticable, an approach to it in practice is to make the hearth a hemisphere.

Hence to reduce the losses of heat from the charge to the least practical, the shape of the hearth should be as near as practical to a hemisphere. As a loss of about 1 kw. per square foot is by no means small, it seems to be important to approach this shape as closely as other practical considerations permit, such; a bath, for instance, would be rather deep, and it might be difficult to get the heat of an arc over the top to flow down to the bottom, which it can do only by slow conduction and possibly some convection.

In a recent article** the writer showed the very great possible economies which might be gained by this one feature of shape alone, especially in such furnaces as those for steel refining in which the chief purpose is to keep the metal at its high temperature. The results showed that for a 10-ton furnace these stand-by losses might in this way be reduced to about 9.5 kw. per ton, even on the basis of a little over 1 kw. per square foot, and to half of this if the insulation could be doubled. At 1 cent per kw-hour the cost of this energy would be only about 10 cents per ton per hour, which is certainly not great.

Heat Emission from Surfaces.—When heat flows out through an insulating wall it meets with some resistance when it passes from the outside surface to the air. For high densities of the heat flow this resistance may be quite great. It is this surface resistance which in part determines what temperature the outside of the furnace will assume when the heat leakage flows out and it will also in part determine the amount of leakage.

Our knowledge of these skin resistances, if they may be so called, is somewhat meager, especially of the laws governing their values. But even if we did know the laws, the actual conditions may be so different from the theoretical ones that the results might be very different from those found by calculation. For this reason it seems best, until better information exists, not to attempt any theoretical calculations but to be guided by actual experimental results.

For this purpose the writer has compiled tables reduced from values gathered from various sources, giving the amounts of heat flowing across such surfaces and the existing temperatures.* The heat flows are there reduced to watts, the temperatures to centigrade degrees and the skin resistances to thermal ohms; the figures are, therefore, directly applicable to electric furnace calculations.

As far as concerns the outside walls of furnaces, they show the following, which, however, must be understood to be rather crude data, as the results from different sources did not always agree well.

When about one-half a watt per square inch flows into the air from ordinary iron surfaces the temperature will be quite warm to the touch. With about 1 watt it would probably sizzle when wetted. With roughly half a kilowatt per square foot it would be very hot to the touch. At a dull red heat it would probably be losing about 7 to 11 kw. per square foot Bright red hot surfaces of metal are probably losing about 12 to 15 kw. per square foot, but in a still atmosphere like in the inside of a covered resistance furnace, the loss may be only about 4½ to 8.

It will be found from these figures that in well-insulated furnace walls the loss is governed chiefly by the insulation itself and very little by the outside contact resistance, hence the latter need not be given much concern. In other words, all the heat which will leak through the insulation in such furnaces will find its way easily to the air without involving any very high temperatures there.

These surface resistances are, however, of great importance in steam boilers or other structures in which the thermal resistance should be as low as possible instead of as high as possible.

These skin resistances can also be expressed in thermal ohms, and are then merely added to the resistances of the walls. The heat flow will then be equal to the total temperature drop (to the air in this case) divided by this total resistance. But as these skin resistances seem to be of little importance in determining the total leakage in well-insulated walls, it seems unimportant to make more refined calculations for apparatus which is as crude as an electric furnace necessarily is, and in which other governing factors are so variable and the physical constants so inaccurately known.

On ordinary iron surfaces the skin resistance for temperatures of about 60° to 200° C. seems to be about 100 thermal ohms per square inch, hence about 0.7 per square foot, which may be added to the insulation resistance to give the total.

For small laboratory furnaces it might be found worth while to polish the outside, as it seems that a polished surface has a much higher thermal resistance; it is alleged to be about five times that of a rough surface. It will then get hotter and one must not be deceived into thinking that therefore the loss is greater for it is really less. But with a good wall insulation it will probably not make much difference whether this relatively small skin resistance is or is not five times as great. The same effect obtained by a polish may be produced with a thin layer of fibrous or granular material which has a very high thermal resistance. This, however, adds to the thickness.

Outside Temperature.—The question of what relation, if any, the temperature of the outside of a wall bears to the total loss is a somewhat complicated one and has been discussed at considerable length. An analysis of it will be found in an article by the writer in this journal, April, 1911, p. 189, one of the conclusions in which is confirmed by the tabulated results mentioned above, namely, that the skin resistance has but little effect. Another is that for the *same furnace* the loss is least the hotter the outside wall, because the temperature drop through the fixed resistance is then the least, hence $W = T/R$ is then least. It would be a grave mistake, however, to compare different furnaces in this way. If a furnace gets hot on

*This journal, November, p. 590.
**This journal, November, p. 590.

*"Flow of Heat Through Contact Surfaces." This Journal, January, 1912, p. 40.

the outside, the probabilities are that by reconstructing it so that it will be cooler the loss will be reduced. The safest general conclusion is not to be misled by the outside temperatures of different furnaces, a hot one might be a better insulated one than a cold one, but, on the other hand, if it is hot it is likely that it can be improved still more and be made cooler.

Vacuum Pans with Jackets.

By B. Viola.

Member American Society of Mechanical Engineers.

In certain cases for special liquors the vacuum pans are sometimes heated not by means of heating coils, but double bottoms or jackets are provided for this purpose. The results obtained from an evaporator or vacuum pan by this construction are entirely different from those considered in former articles, because the heating steam does not have the same

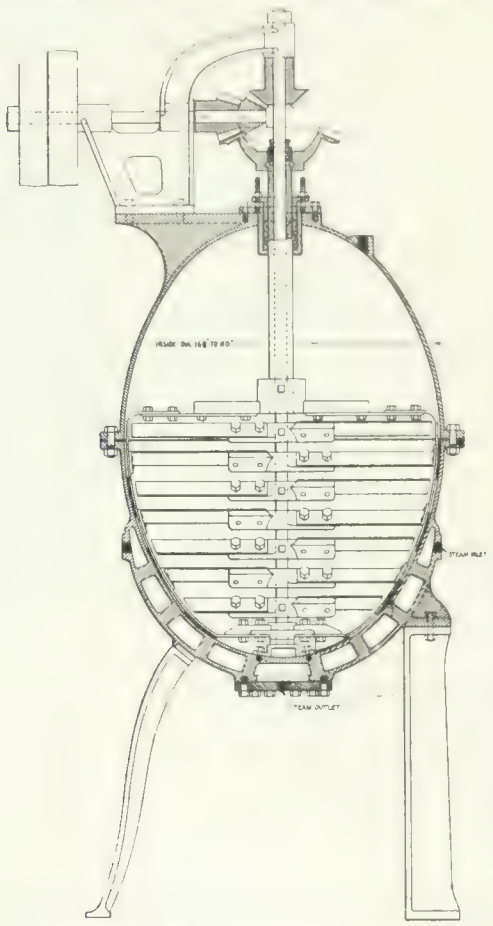

FIG. 58.—CROSS-SECTION OF A CAST-IRON JACKET VACUUM PAN.

uniform effect on all parts of the heating surfaces. The steam does not pass equally over the heating surface with the same compulsory effect; entering at the inlet, the steam spreads in the whole jacket and tries to escape by the shortest way through the outlet. Naturally, therefore, the heating surface does not give the same results as in the case of heating coils or tubes. This is the reason why the heat transmission coefficient on which our former calculations were based (see the article in the January issue) cannot be used in these cases, since it varies too much. The larger the jacket the smaller will be the value of the coefficient. Scales found on the heating surface have also to be taken into consideration.

The efficiency will certainly be the higher the more steam inlets are provided. The evaporative capacity also depends largely on the temperature of the steam, there being, of course, no strict proportionality. Further, with an increase in the temperature of the boiling liquid the heat transmission increases.

Moreover, the steam always carries a certain quantity of air, which prevents its close contact with the heating surface; this has also to be taken into consideration. This air then escapes through the exhaust line, which always has to be placed in the lowest point of the jacket.

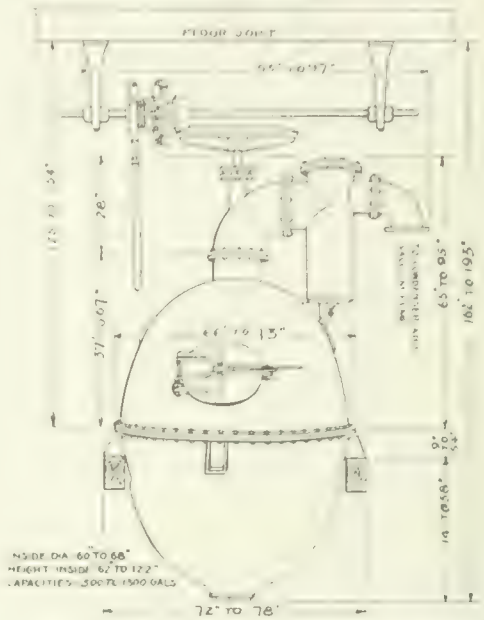

FIG. 59.—VACUUM JACKET VACUUM PAN WITH FLOOR CATCHER.

In general the transmission of heat by a copper double bottom can be expressed, by using the formula 1 from our previous article (January issue, page 31), in the form:

$K_v = 1400$ to 1800 C calories per square meter an hour; the smaller the diameter, the larger is K_v and vice versa.

The incrustation of the heating surfaces alters considerably

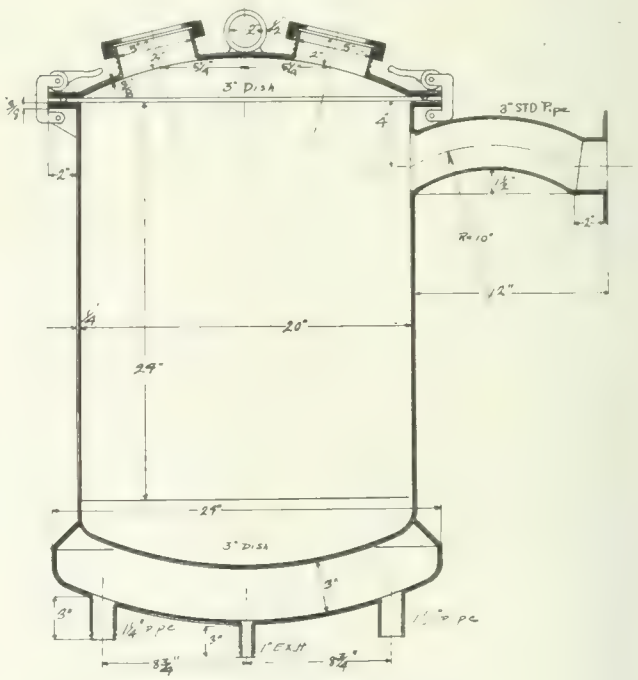

FIG. 60.—ENAMELED EVAPORATOR WITH DOUBLE BOTTOM.

the value of the heat transmission and our former formula (2) for the heat Q may be changed as follows:

$$Q = \frac{H\,C}{2}\,(t_2 - t_1)$$ calories per hour for a double bottom of copper, where

H = heating surface in square meters.

C = heat transmission coefficient in calories per square meter per hour.

t_2 = temperature of heating steam.

t_1 = temperature of boiling liquid.

To give the results in a more practical form we may say that copper-jacketed kettles will evaporate at the same steam pressure about 4 to 2.5 gal. per hour and square foot, while the diameter varies between 1.5 to 10 ft.

Cast-iron vacuum pans of the Dopp system are shown in Fig. 58 in cross-section and in Fig. 59 in perspective view equipped with pulley drive and with juice catcher and friction clutch drive respectively.

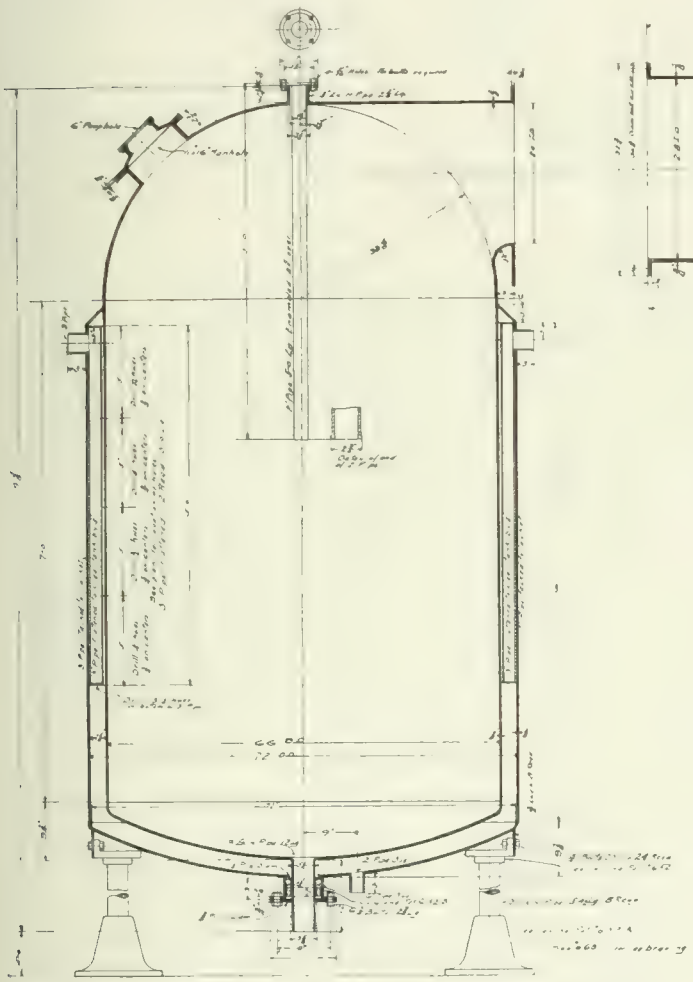

FIG. 61. ENAMELED JACKET VACUUM PAN EQUIPPED WITH JET CONDENSER.

It may be stated here that these vacuum pans are also equipped with double-motion agitators and Fig. 58 shows this type of construction, used in sizes ranging from 10 to 500 gal. The outlet is not shown in the drawing, as this is furnished in different styles, according to the different kinds of work they are to handle.

The bottom of this pan is made up of a seamless steam-jacketed kettle which is cast by a special process, rendering them absolutely smooth and free from the possibility of leaky rivets, stay-bolts or joints.

The shells are reinforced by stay-bolts, these stay-bolts being cast at the same time as the shells.

Fig. 59 shows the same type of vacuum pan for a total capacity of from 600 gal. to 1300 gal., equipped with a single-motion drive.

The following results were obtained with the above mentioned Dopp cast-iron vacuum pans of 300 gal., with a heating surface of 17.34 sq. ft.:

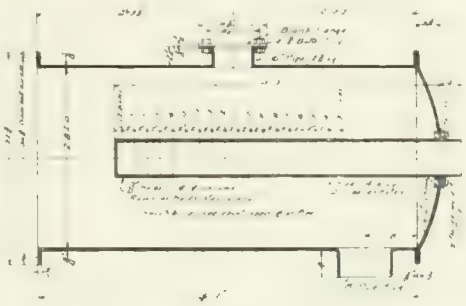
Feed at temperature of vacuum

Vacuum.	Steam pressure in jacket.	
	80 lb.	120 lb.
24 in.	44.37 gal.	51.50 gal.
26 in.	49.50 gal.	56.89 gal.

Feed at temperature of 60 deg. Fahr.

Vacuum.	Steam pressure in jacket.	
	80 lb.	120 lb.
24 in.	41.11 gal.	47.8 gal.
26 in.	46.67 gal.	53.6 gal.

The number of square feet of heating surfaces in these various pans ranges from 1.695 in the 10-gal. pan to 55 in the 1000 or 1300-gal. pan. In the 300-gal. pan it is 17.34 sq. ft.



For the evaporation of certain acids or milk, the so-called vitreous-enameled steel vacuum pans can also be used satisfactorily.

This enamel does not contain metallic oxides, such as those of lead, tin, arsenic, etc., since in its chemical composition it is practically all quartz. This makes it not only acid-proof, but absolutely non-poisonous, so as to meet the strictest requirements of the pure food laws of all governments. This vitreous enamel has all the chemical-resisting qualities of plate glass, but does not have its fragile qualities; it is actually fused into the steel at a temperature of about 3000 deg. Fehr., so that there is absolutely no danger of cracking, crazing or scaling due to expansion or contraction from alternate heating or cooling.

Further below I am showing the types which are mostly used in the evaporation of milk products and certain acids.

Fig. 60 shows a small enameled steel vacuum pan with double bottom and two steam inlets and one exhaust outlet in the center of the bottom.

Below the cover there is provided the neck-connection to the condenser.

For emptying this vacuum pan the top cover is removed, which also contains two peep holes.

Fig. 61 shows an enameled vacuum pan with double bottom and side jacket. In connection with the two side steam inlets, another inner pipe can be seen, which is provided for the purpose of protecting the inside kettle from impact of the steam. This arrangement has proved very satisfactory in practice. This also helps distribute the steam at the bottom of the tank and to cause a much better circulation.

On the upper right-hand side there is a horizontal pipe with an inner pipe of much smaller diameter in the center. It is connected with the vapor outlet on the top of this vacuum pan. It serves as a condenser for the escaping vapors, cold water entering the center-pipe, which is perforated on the top and works as a jet condenser.

Fig. 62 is another type of a vitreous enameled jacketed vacuum pan.

It is provided with all the necessary openings needed for the control of the evaporation of the liquor.

Fig. 63 is the same vacuum pan connected with an enameled juice-catcher (the author's construction).

The evaporative capacities of these enameled vacuum pans are proportional to the heat transmission capacities of the material of which they are made as compared with copper. These data were mentioned in some of the previous articles. I may refer here only to Fig. 49 in my article in the issue of July, 1911, of this journal (Vol. IX, page 354), showing a homogeneous lead-lined jacket evaporator, figures of its capacity being given on page 352.

Calculation of Furnace Charges—II.

By Regis Chauvenet.

In considering analytical data from which slags and mattes are to be computed regard must be had to the questions: which of the elements are presumably reducible to metal,

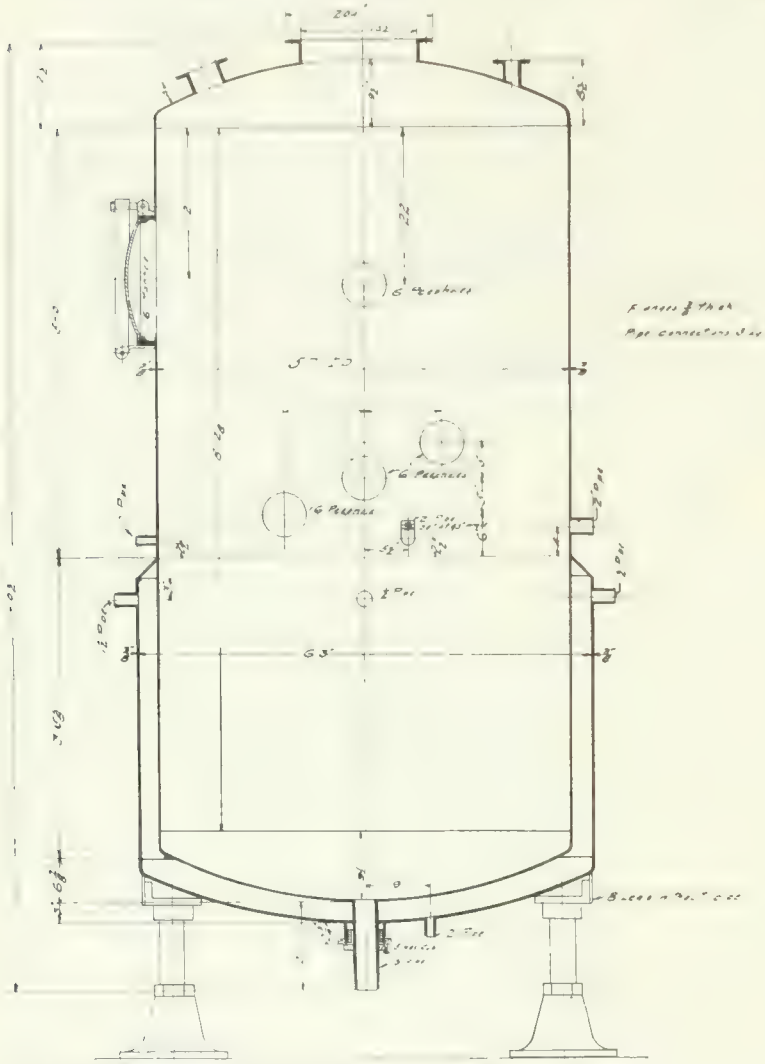


FIG. 62.—CROSS-SECTION OF ENAMELED JACKET AND PAN

which are volatile, whether as gases or as "fumes", which will enter the matte, and finally, which will combine to form the "slag," whether of themselves or by combination with other materials, added for the purpose, which may be grouped under the broad term of "fluxes." Frequently the flux carries "values" also, but this is a feature which we propose to omit in the present treatment of the topic.

We shall describe the various requirements, in a theoretical sense, of slags, then show how to "take out" the matte, next how to adjust the bases so as to simplify the calculation, and finally, before proceeding with the actual calculation of charges based on analyses of materials, we shall give a few types of slags (analytical) for iron, copper and lead furnaces.

Formulistic and Percentage Slags.

We may take up (a) "formulistic" slags, in which the requirement is that its composition shall show a definite chemical formula, and (b) "percentage" slags, whose requirement is simply as to percentage of certain elements, frequently limited to percentage of silica only.

In the Chemical Introduction, however, we have already shown that any formula may be quickly transformed into an analytical statement. Later, in setting forth the method recommended as the most general for all slag computations, we instruct the computer to start his computations by putting his required "formula," if he is to figure on that principle, into the percentage shape before proceeding.

We may subdivide formulistic slags again, roughly, into two classes. The first of these we call true formulas, viz.: Not only is the silica properly adjudicated to each base, but the bases themselves are in a definite chemical relation *to each other*. Not always can such slags be produced by pre-adjustment of material, unless the ore used is of exceptional simplicity in composition. Conventionally, by the transformation (on paper) of one base into the "equivalent" proportion of another base, such formulas may be brought about, as will be shown later in the present article. Such adjustments are useful; their limitations, however, should be understood.

To illustrate the theory of a perfectly formulistic slag, suppose we require that our slag shall have the formula:

$$Fe_2SiO_4 + Ca_2SiO_4$$

in which expression Fe and Ca must be regarded as having their atomic ratios, i.e., 56 and 40. This formula is better written:

$$(FeO)_2SiO_2 + (CaO)_2SiO_2$$

so as to show at a glance the "singulo" form, i.e., oxygen in the base equal to oxygen in the silica. We shall retain hereafter the old "dualistic" form for these and other silicates.

This would be called a perfectly "formulistic" slag. Again, we may require that the slag shall contain two molecules of ferrous silicate to one of lime silicate, or:

$$2\,(FeO)_2SiO_2 + (CaO)_2SiO_2$$

In these and similar cases we may call the slag "strictly" formulistic.

In practice, however, another form will be far more common, the one, namely, in which, although we can obtain the proper relation of silica to each base, it is not practicable to obtain a definite relation in a chemical sense of the bases *to one another*.

We are here considering only the case of di-basic slags.

Such a slag we may call, to coin a term, "semi-formulistic."

For example, retaining iron and calcium for illustration, we may have a slag whose general form is:

$$x\,(FeO)_2SiO_2 + y\,(CaO)_2SiO_2$$

in which x and y are in their relation to each other indeterminate. Such a slag is still a "singulo" silicate in that the oxygen ratio of silica is maintained, but it is no longer in the perfect form indicated in the first example.

Percentage slags may also be classified, though for the purpose of this article this is not necessary. It is no infrequent matter to see a furnace run on the simple requirement that the slag shall show the silica always between certain limits, ex. gr., 35 to 40 per cent.

As we have already shown how to transform any formula into percentage, and have further indicated that we shall show how to calculate any slag in this manner, it might well be asked: "Why go into formulas at all?" There are several reasons: we content ourselves here with the general one, that it has been found unadvisable to omit methods by "excess" entirely. There is no escaping it in "taking out" a matte, and there are other cases where it is better to have a knowledge of chemical relations. This becomes indeed indispensable for the reading of most metallurgical works, in which such knowledge is assumed on the part of the reader. Having, then, outlined these principles, we shall show how to apply them in certain cases. It will soon be seen that as complexity in the problem increases, the method by "excess" becomes more and more difficult, and

per contra, the method by equation applies as well to the complex as to the simple problem.

Calculations for Matte.

Before analyses of material can be subjected to calculation for the furnace charge, they must first undergo two preliminary clearances. The first of these is the "taking out" of the matte. The second is the adjustment of bases, sometimes called "adjudication," by which is meant the allotment of certain of them, in their respective chemical ratios, so as to classify several bases under one head.

Both of these have as objects the simplification of the subsequent calculation for slag formation.

It is necessary that the calculation for matte should come first. It is only when all the bases which may be supposed to form matte or speiss are removed (i.e., by calculation) from the data that we can proceed to compute the reactions of silica with the bases remaining.

Briefly: Since in the actual operation of the furnace the sulphur and its accompanying metals drops out in the form of matte, leaving the slag as a separate product, so in the computation we take out, theoretically, what the furnace is expected to do actually.

Then (matte being out of the way) before computing the relations of the slagging materials it has long been seen that the attempt to formulate each base into line was a problem far more curious than practicable, when the bases exceeded two in number. Hence the practice, familiar to metallurgists, of conventionally transforming bases into their chemically equivalent quantities as compared with either iron oxide or lime.

A "matte" is chemically very difficult to define. We are here concerned but little with the theory of its formation. Essentially, it is a complex sulphide, which separates, owing to its greater specific gravity and also because of its radically different chemical nature, from either metal or slag, sinking below the latter in the operation of smelting. A "speiss" is a basic arsenide, often of iron alone, sometimes with other metals, formed under conditions entirely similar to those which give rise to matte.

A matte may be the only commercial product in smelting, in which case its composition almost invariably includes both copper and iron. This is not a treatise on working conditions, hence much is omitted that does not bear directly on the subject of computation. We merely note here that matte is often formed when the chief product is metal (especially in lead smelting), and that in somes cases its expected total weight is so small that computations are made without regard to it.

We are confronted with uncertainties in matte calculation. Given, let us say, an ore which has been partially roasted, but which still contains a considerable percentage of sulphur, the estimate as to how much of that element will be dissipated (in fumes or gas) and how much will be found as a true "product" in the matte is a matter rather of special experience than of calculation.

This experience has regard to composition of the charge, degree of oxidation, and conditions which determine the latter, ex. gr., shape of the furnace, blast, fuel ratio and other considerations. In the extreme case of "pyritic" smelting, especially when the ratio of coke is small, nothing but practice based on careful observation will serve to maintain the desired balance. A function of the blast (aside from its burning the fuel proper), is to burn both sulphur and iron, the burnt sulphur leaving the stack as SO_2, the burnt iron entering the slag as silicate. The residual (unburned) sulphur combines or retains its combination with unburned metals to form the compound known as "matte."

Various assumptions may be made as to the conduct of sulphur in the operation of smelting, and as to the distribution of the metals as well. Thus, zinc in the same run, may be found in fumes, matte and slag; so may lead. Iron is almost invariably divided between matte and slag (in operations where any matte is formed), while copper which in the matting furnace should be thrown entirely into matte, may by excess of oxidizing influences be carried into the slag to an extent destructive of profits.

Hence it is that writers on the detail of matte estimation are disposed to base the calculation upon certain assumptions regarding the probable destination of fractional parts of both sulphur and of metals. These assumptions are themselves based upon actual experience. Having made them, ex. gr., having assumed that one half of the sulphur will enter the matte and that one fourth of the zinc will be carried into fumes, the sup-

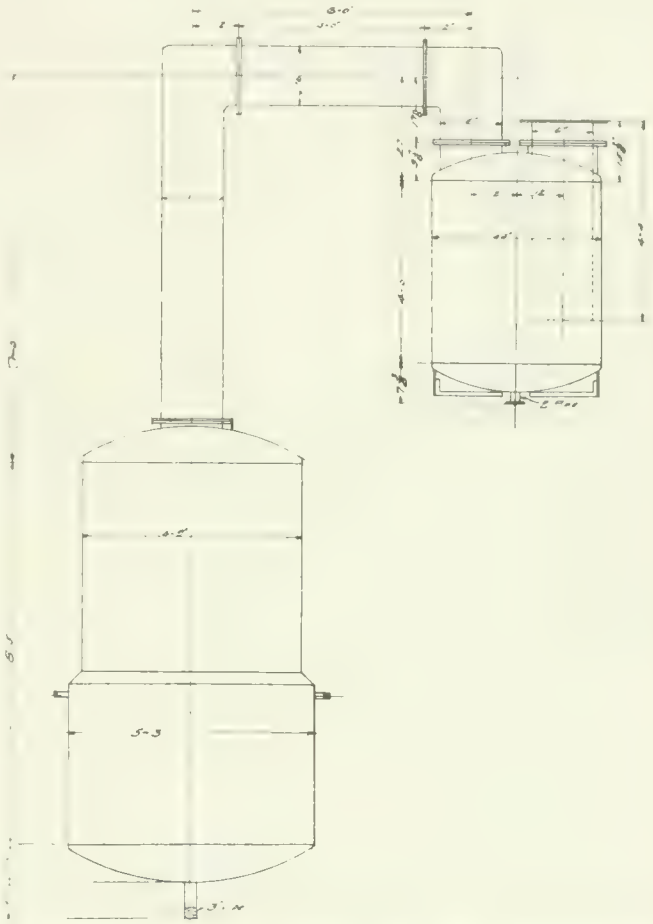

FIG. 63 ENAMELED JACKET VACUUM PAN WITH JUICE CATCHER

posed residual quantities will form the basis of our calculations. Estimates of this kind are liable to considerable uncertainty if the furnace varies much in action, as, to cite a not uncommon case, when oxidation falls below its expected total, resulting in too high a percentage of iron in the matte, with corresponding low percentage of copper. The reverse of this condition might lead to oxidation of copper and its consequent unprofitable presence in the slag.

These remarks are sufficient to indicate the distinction we make between "guesses" as to these distributions, and the calculations based on them. Generally, the computation of matte formation lacks the accuracy of a slag calculation, which is based upon a mixture free or nearly free from the "side issue" of matte fall.

Calculations for matte should always be based on stoichiometric data, i. e., on chemical ratios according to atomic or molecular weights. These, however, are of the simplest description, and may be briefly epitomized in the general statement that copper is computed as its subsulphide, Cu_2S, iron as FeS, while zinc and lead, when it becomes necessary to provide for them at all, may be put in as ZnS and PbS respectively. We shall not consider the mattes resulting from further "concentration," which may be considerably lower in sulphur.

As we have assumed the atomic weight of copper as 64 for these computations, we "adjudicate" copper subsulphide as 128 copper to 32 sulphur, that is, as 4:1.

Iron, as FeS, takes the ratio of 56 to 32, always simplified into 7:4.

Zinc sulphide whose exact ratio is Zn 65, to S 32 may be safely computed in the ratio of 2:1.

Finally, lead sulphide, whose exact ratio is Pb = 207 to S = 32, is not reducible to any very simple ratio; 65 to 10 is quite close enough, but does not gain much over the original weights in simplicity.

In the common case of very small weight of lead figured into matte, six to one would suffice.

We now give our first example, making it simple both as to composition and as to the assumptions.

Examples. (a) Partially roasted ore contains:

Copper	7.6 per cent
Iron	16.8 per cent
Sulphur	7.0 per cent

Assume that all of the copper and all of the sulphur will enter the matte and that all iron will enter the slag except as taken by the sulphur left after the copper is satisfied. If we taken 100 lb. of ore, what will be weight of the matte and what will be its analysis?

Solution. We start (as always) with the copper, as the metal with the greater affinity for sulphur. We have:

Cu$_2$: S = 4 : 1 = 7.6 : 1.9

that is, the copper will take up 1.9 lb. of sulphur. Subtract this 1.9 from total sulphur of the analysis: 7 — 1.9 = 5.1; this 5.1 is the sulphur which is to be apportioned to iron. The latter being obviously in excess, it is convenient to place sulphur first in our next proportion.

S : Fe = 4 : 7 = 5.1 : 8.9

neglecting second decimals of a pound. That is, 8.9 lb. of iron will go into matte. We have now for the weight and composition of the matte:

	lb.	Percentages.
Copper	7.6	32.34
Iron	8.9	37.87
Sulphur	7.0	29.78
Weight	23.5	99.99

No "predicted" analysis can in practice be stated thus accurately. In this case the rough approximation: Cu = 30, Fe = 40, and S = 30 would be as close as could be reasonably expected.

(b) We have in an ore:

Copper	3.00 per cent
Iron	10.00 per cent
Sulphur	4.00 per cent
Arsenic	1.00 per cent

Take out matte and speiss, under the assumption of no losses, figuring speiss as Fe_5As. (Simple ratio for As to Fe is 15 : 56.)

First figure out the copper, then the arsenic, then remaining sulphur to remaining iron.

Cu$_2$: S = 4 : 1 = 3 : 0.75

As : Fe$_5$ = 15 : 56 = 1 : 3.7

S : Fe = 4 : 7 = 3.25 : 5.7

From the 4 per cent sulphur we take the 0.75 required by copper; remains 3.25 which figures in the last proportion. Iron taken is: by arsenic, 3.7; by sulphur, 5.7; total, 9.4 lb. Total lbs. and analysis of matte:

Matte and Speiss	lbs.	Analysis.
Copper	3.0	17.24 per cent
Iron	9.4	54.02 per cent
Sulphur	4.0	22.99 per cent
Arsenic	1.0	5.75 per cent
	17.4	100.00 per cent

We here quote from Prof. Peters' work on "Modern Copper Smelting."

"Taking the contents of copper in the charge as a standard for comparison, sufficient sulphur should be alloted to it to form Cu_2S, excess of sulphur remaining being supplied with sufficient iron to form FeS. If other metals are present such as lead, zinc or manganese, three fourths of the former, one half of the second or one fourth of the latter may be first considered as forming monosulphides. If the rate of smelting be slow, and considerable lime or magnesia be present, 5 per cent of the sulphur should be deducted before beginning the calculation, and if the furnace be a reverberatory the resulting matte will average 8 per cent higher in copper than is found by this formula."

This must be considered as applying to copper smelting only, not at all as to lead or other metals.

We give an example based on the above assumptions of Prof. Peters. However, there is not the slightest difference in method under any "assumption" since the latter requires only certain subtractions to be made before starting the adjudications.

(c) We have an ore which analyses as to matte ingredients:

Copper	5.0 per cent
Iron	[illegible] per cent
Zinc	6.0 per cent
Lead	2.0 per cent
Sulphur	8.0 per cent

"Take out" the matte under the above suggestions of Prof. Peters, also allowing that 5 per cent of the sulphur is excluded from the matte. This leaves 7.6 per cent sulphur for the computation, 1.5 per cent lead and 3 per cent zinc.

We have:

Cu	S	4	1	1.25
Zn	S	2	1	1.50
Pb	S	65	10	0.23
				2.98 required sulphur.

Let us say 3 per cent sulphur for the three metals considered, then taking this from the 7.6 "available" sulphur we have left 4.6 per cent to be adjusted to iron. Iron is in excess over sulphur remaining; put sulphur first in your proportion.

S : Fe = 4 : 7 = 4.6 : 8 = lbs. iron.

We may now write composition of the matte in pounds, also analysis. The latter we state to nearest whole figures only.

Matte, lbs.		Analysis.
Copper	5.0 lbs.	20 per cent
Iron	8.0 lbs.	32 per cent
Zinc	3.0 lbs.	12 per cent
Lead	1.5 lbs.	6 per cent
Sulphur	7.6 lbs.	30 per cent
	25.1 lbs.	100 per cent

Adjustment of Bases.

Having shown how to set aside the elements for matte-fall with greater or less accuracy, we come to the final preparation by substitution of bases. It is true that there are other allowances to be made, for possible losses by volatilization, but these can hardly be formulated. They may be reduced, by careful observation of furnace products, to some definite figures, after which, if necessary, due allowance may be made for them in the charge.

If, for example, in smelting an ore high in zinc, analysis of the products shows a loss of one-fifth of same, unaccounted for, such a loss would become part of the computation data. However, such allowances are merely omissions of the presumed losses from the weights or percentages shown by the analyses.

It has already been said that it may be a matter of complexity to make separate figures for each and every base. Accordingly, we "lump" two or three bases into one calculation. This may be done in either one of two ways, viz.:

(1) Weight for weight.
(2) Stoichiometrically.

A third method has been recently called to the writer's attention. It has the merit of extreme simplicity, and consists in treating a certain base as if it did not exist, i. e., calculating the charge without the least reference to it, and "trusting to luck" that it would be "carried." The only base so far known to have been treated in this manner is alumina, and that only to a maximum of a possible 10 per cent in the slag.

There is, however, a quite common practice of calculating a slag on the basis of 90 per cent total, instead of 100, putting silica in the calculation a little higher than necessary (theoretically), and explaining the procedure much as above, viz.: the 10 per cent deficit in the calculation represents unreported (or neglected) bases, and, like the operator who disregards his alumina, the smelter "trusts to luck" and silica to see him through.

Returning to (1). Suppose we are to compute a charge, and that we have an ore with:

Fe_2O_3	10 per cent
MnO	3 per cent

Also, we have a limestone with:

CaO	50 per cent
MgO	2 per cent

We know that FeO = 72 and MnO = 71 in molecular weights. It is useless to apply such minute differences in practice. In this case we should "prepare" the ore for its slag computation by taking 0.9 of the Fe_2O_3 as $(FeO)_2$, and adding the MnO, thus:

Iron oxide, 10 × 0.9	9 per cent
MnO =	3 per cent
FeO =	12 per cent

As to the limestone, it is hardly worth while to consider 2 per cent of MgO stoichiometrically. Note that it is only because of the small percentages that this case is so summarily dismissed. We would here say "CaO 52 per cent" and proceed so to calculate; that is simply adding the MgO to the CaO.

This "weight for weight" will sometimes serve, and often does, but it is better to come at once to plan (2) and make stoichiometric substitutions, i. e., by relative atomic weights. There is much that is conventional about even this method of treatment, albeit it may become necessary.

The assumption underlying this substitution of one element for another must be that the displacing element will act in a manner similar to the one displaced. As there is no actual displacement, we might better say that we assume that each element will, when used in its atomic ratio, act in the same manner as the one to whose basis we figure it. This is by no means always true, the simplification by this artifice being a convention for the reduction of slags to certain "type" forms.

Take the case of zinc oxide. If we have to treat it as the component of a slag it must go into the lime group, and its percentage will be multiplied by 0.7. (Example, if we had 7 per cent zinc we should compute it at 7 × .7, say 5 per cent.) The result will be that, in computing for addition of limestone to the flux, we shall use less lime, because we have already a certain amount of "conventional" lime in the shape of calculated lime, which is really zinc.

Here is a case "by contraries" instead of by similarities. The more lime in the slag the worse the carrying power for zinc: in fact there comes a point where the slag refuses to carry any more zinc, and when the slag is very high in lime it cannot carry zinc at all.

Thus, putting zinc into the lime column is far from indicating that the two act alike, but a purpose is subserved nevertheless, for the *actual lime* is diminished, as it should be if the addition of zinc is inevitable.

The process of substitution of one base for another consists simply in computing a given weight of a certain base into its equivalent weight in another base, these "equivalent" weights being in the ratios of the molecular weights of the bases.

Illustration. We have a limestone whose analysis shows CaO, 39 per cent, MgO, 9 per cent. Stoichiometrically, we have:

MgO : CaO = 40 : 56 = 1 : 1.4

That is, one part of MgO can carry as much silica as 1.4 parts CaO. Accordingly we may multiply MgO by 1.4 and then add in the product as CaO.

Thus, 9 × 1.4 = 12.6 and in our computation for limestone in slag we get:

CaO by analysis	39.0 per cent
CaO by conversion	12.6 per cent
Conventional lime, for computation	51.6 per cent

The excess figured from the analysis *is not affected by this substitution*, a point we leave the student to verify for himself.

Conversion Factors.

Iron and Manganese. The metals have as atomic weights 56 and 55, their protoxides are FeO = 72 and MnO = 71. Hence it is not worth while to use any factor. Reduce all iron to basis of FeO, and all manganese to basis of MnO if not already so reported, then add the FeO to the MnO as in above example.

Alumina. This acts sometimes as acid and sometimes as base. We here dismiss the case of the acid action of alumina. Opinions differ as to how to group it. We have already noted that some "dodge" the question by not including it at all in apportionment of base to silica.

Take any of the ordinary relations, say bi-silicate, we have:

$Al_2O_3 . 3SiO_2$ and $(CaO)_3 . 3SiO_2$.

In relation then, to saturating power we have Al_2O_3 : 3CaO = 102 : 168 and since 102 : 168 = 1 : 1.65, we may assume 1.65 as factor for "conversion" of Al_2O_3 into CaO.

Magnesia. This has already been shown to have factor 1.4. Example, 10 per cent MgO = 14 per cent CaO.

Baryta. BaO : CaO = 153 : 56. In this case we have a factor much less than unity. Strictly, 153 : 56 = 1 : 0.366, but in practice 0.4 has been adopted.

Zinc. ZnO : CaO = 81 : 56. The factor adopted for "converting" ZnO into CaO is 0.7.

Those last two, (Ba, Zn) are not desired in any slag. Zinc is the more objectionable. The action of barium is somewhat uncertain, as under strong reducing action in the presence of sulphur its sulphate drops to sulphide, and joins the matte, chemically at least, though not always separating well.

Examples of simplification. (a) We have an ore whose analysis give (slag constituents only):

Silica	28 per cent
Ferrous oxide	36 per cent
Alumina	8 per cent

Also a limestone, analyzing:

Silica	6 per cent
CaO	46 per cent
MgO	4 per cent
Al_2O_3	4 per cent

Simplify these by substitution, according to rules above: *Answers.*

Ore.		Limestone.
Sio_2 28	per cent.....	6 per cent
Feo 36	per cent.....	.....
CaO..... 13.20	per cent.....	58.2 per cent

(In ore 8 × 1.65 = 13.20. In limestone 4 × 1.4 = 5.6 and 4 × 1.65 =6.6. 46 + 5.6 + 6.6 = 58.2 per cent lime.)

One more example will illustrate a complete operation, viz.: both the "taking out" of the matte and the subsequent adjudication of bases.

(b) Take the following copper ore analysis; *assume* that one-third of the zinc goes off in fumes, one-third into the slag.

one third into the matte, all copper goes into the matte, one fourth of the sulphur is dissipated; also, in matte formation the copper and the one-third of the zinc take precedence of the iron, so that it is only the "residual" sulphur that can be apportioned to the latter metal. We figure on 100 lb. of ore.

Then, the matte being out, simplify the bases and present revised analysis as basis for slag computation.

Original Ore Analysis.

Silica	36	per cent
Alumina	8	" "
Baryta	4	" "
Magnesia	6	" "
Lime	6	" "
Manganous oxide (MnO)	4	" "
Iron (metallic)	12	" "
Zinc	6	" "
Copper	6	" "
Sulphur	9	" "
Deficit (Oxygen, etc.)	3	" "
	100	" "

Solution. One-fourth of 9 per cent sulphur = 2.25. Sulphur available for matte = 6.75.

Cu : S 4 : 1 6 : 1.5 = S in Cu S

Zn : S 2 : 1 2 : 1 = S in Zn S

Sulphur with Cu and Zn = 2.5

6.75 − 2.5 = 4.25 = S for FeS.

Also, S : Fe = 4 : 7 = 4.25 : 7.46 = Fe in FeS.

Now figure pounds and analysis:

	Pounds.	Analysis.
Copper	6	27.0 per cent
Zinc	2	9.0 " "
Iron	7.46	33.6 " "
Sulphur	6.75	30.4 " "
	22.21	100.0 " "

We now simplify the bases, by factors shown above. Ore, with matte out and bases "converted" reads as follows:

Silica	36.00 lb.
CaO	30.95 lb.
FeO	0.84 lb.

The CaO is made up as follows:

Al_2O_3	8	× 1.65	=	13.20
BaO	4	× 1	=	1.60
MgO	6	× 1.4	=	8.40
CaO	6	× 1	=	6.00
ZnO	2.5	× [illegible]	=	1.75
				30.95

The Electrolytic Determination of Lead in Large and Small Amounts, Using a Gauze Cylinder Anode.

By Bruno Wollenberg.

Among the articles published by various workers on electrolytic methods for the determination of lead, there seems to exist a lack of description of exact conditions necessary for the rapid deposition of PbO_2 on a gauze cylinder anode with a rotating cathode.

Prof. E. F. Smith in his book on Electro-Analysis recommends the use of a sand-blasted platinum dish to secure an adherent deposit, but in a technical laboratory the use of a dish is not practicable.

J. G. Fairchild describes in the *Journal* of Ind. and Eng. Chemistry conditions that must be observed to get a good deposit on a smooth cylinder with stationary electrodes. This is of merit, although the amount of PbO_2 that can be obtained in an adherent condition is limited to 0.3 gram.

The conditions that are good in these cases are not satisfactory when different forms of electrodes are used.

At present, most of the metallurgical laboratories that are using electrolytic methods are furnished with gauze cylinders and rotating propeller-shaped anodes. The description of conditions that have been found necessary in this laboratory to obtain a good deposit of PbO_2 on a gauze cylinder will, no doubt, be of some value to those who are using this device.

The method, as it is used for lead base babbitts, is as follows: The tin and antimony are separated from the lead and copper by means of sodium sulphide. The sulphides of lead, and copper when it is present, thus obtained, are dissolved in a known amount of HNO_3 (10 cc), filtered, the sulphur and filter paper burnt, the residue dissolved in a little HNO_3 and added to the main solution, which should be in a tall electrolytic beaker of 200 cc capacity. Sufficient HNO_3 is added to make a total of 45 cc of strong HNO_3 in 150 cc of solution.

The electrolyte is heated till it starts to boil and electrolyzed with 3 amp for a minute or two, or till the deposit is brown in color, then with 5 amp for 20 to 30 minutes.

The deposit must be dried at the usual temperature for PbO_2, viz.: 230 deg. C. for 20 to 30 minutes, depending on the amount of deposit.

The conversion factor is used as given by Prof. Smith, 0.8643, instead of the theoretical 0.8660.

The deposit will be so adherent that it will not come off when rubbed with the finger; a finger nail may scratch it off, however, so the electrode must be handled with care while disconnecting, drying, and dessicating. It is a good idea to have in the drying oven an adjustment for hanging the electrode. A binding post fastened to the wall of the oven will answer the purpose very well.

When other metals, especially copper, are present in large amounts, and Pb does not exceed 10-12 per cent, the amount of HNO_3 may be considerably reduced, and this is usually the case with brasses. In this case to the filtrate from metastannic acid sufficient HNO_3 is added to have 10 cc in a total volume of 150 cc. The solution is heated to boiling and electrolyzed with 5 to 6 amp for 15 minutes. The deposit will range in color from golden brown to dark brown and may be dried completely at the usual temperature of the drying oven, viz., about 105 deg. C.

If copper is to be determined after lead it will be found better to have more HNO_3, say about 20 cc, in 150 cc of solution. Then less Cu will be deposited on the cathode, which must be dissolved off before neutralizing and subsequent acidifying the solution for Cu deposition.

At present this laboratory uses a magnetic rotating apparatus called the Frary solenoid, a description of which may be found in "Electro-Analysis," by Smith, and in "Technical Analysis of Brass," by Price and Meade. It has proven to be the best apparatus adopted for the deposition of PbO_2 especially when lead is present in very large amounts. The conditions are identical with those described for a rotating anode device. With this apparatus a number of depositions of PbO_2 are made daily, the amount of PbO_2 deposited ranging from 0.0005 gm to 2.00 gm, without any difficulty.

In conclusion, therefore, the author feels justified in highly recommending the solenoid, as it gives the most satisfactory deposits, not only of PbO_2 but of all the metals which can be electrolytically determined.

Lunkenheimer Bearing Company, Buffalo, N. Y.

Of the "Chemist-Analyst," the excellent little journal published periodically by the J. T. Baker Chemical Company, of Phillipsburg, N. J., No. 3 has just appeared and contains besides useful information on various analyses, an illustrated article on the manufacture of chemically pure nitric acid, an article by George J. Hough on the determination of iron, and a description by George R. Michener of a convenient wash-bottle mouthpiece.

The Production of Oxygen in the Workshop.

The Production of Oxygen from Bleaching Powder.

By Aug. S. Neumark

The precise nature of bleaching powder (chloride of lime) has not been satisfactorily demonstrated; but it is generally regarded as a chemical combination of calcium hypochlorite and calcium chloride, which may be expressed by the chemical formula: $CaOCl_2$. It also contains small quantities of basic calcium hypochlorite CaOCl.OH and basic chloride CaCl.OH, and there is always present an excess of lime and a certain quantity of water. It is manufactured by electrolytical processes in various strengths containing anywhere between 20 and 40 per cent of available chlorine.

That bleaching powder could be used for the production of oxygen has been known since 1829, when Dingler first obtained this gas by heating chloride of lime with certain metallic oxides (cobalt, nickel and copper). Later the wet process of decomposing bleaching powder was resorted to and various methods were subsequently proposed by Mitcherlich, Stalba, Winkler, Fleitmann, and lately by Jaubert.

If a clear and concentrated solution of the powder, to which has been added a small quantiy (0.1 = 1 per cent) of the oxides of cobalt, nickel, copper or iron (or the salts of such oxides), is gently heated to 70 to 80 deg. C., 158 to 176 deg. Fahr., oxygen gas is given off in a slow and regular stream. It is not necessary to heat any further, since when once started the reaction continues until all the oxygen from the hypochlorite has been disengaged.

Instead of a solution, a paste made of bleaching powder and water may be used. In that case, however, it is necessary to add some paraffin oil, or a piece of paraffin. The oil or the molten paraffin, floating on top of the pasty liquid, prevents frothing of the mixture, which otherwise would occur. The oxygen escapes with effervescence in quantities equivalent to the active chlorine.

Although a number of salts and oxides (ferric hydrate or manganese dioxide may also be used) may serve as a contact substance, it seems that cobaltic oxide (cobalt peroxide) is the one which is most prompt and energetic in its action, and that relatively small quantities of it are required for the reaction.

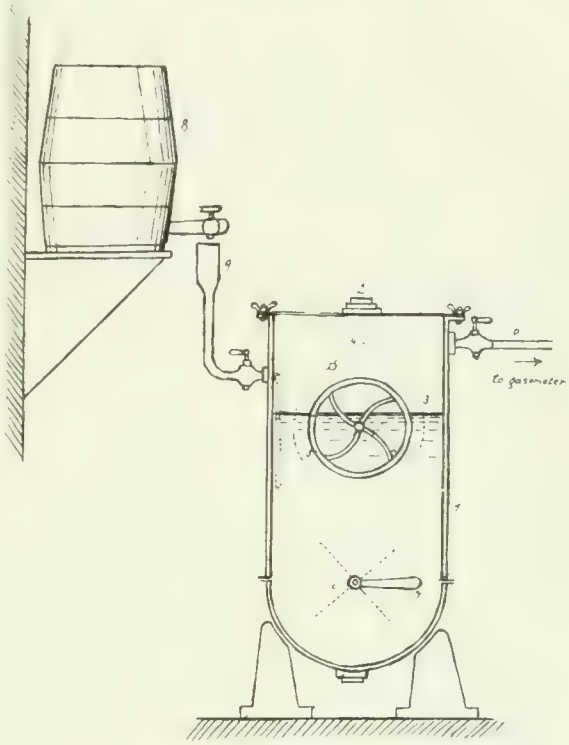
The oxygen obtained is quite pure: the free lime which is always present in the bleaching powder sufficiently prevents the disengagement of chlorine.

A modification of this process is the one proposed by Fleitmann. A suitable vessel is filled with milk of lime to which has been added some cobaltic oxide. A constant stream of chlorine is then allowed to pass through the fluid, causing the disengagement of a like amount of oxygen. The latter will be found to be almost free from chlorine, even if the gas should be introduced in a rapid stream. Only when the calcium hypochlorite is entirely decomposed will the oxygen be mixed with chlorine, which can easily be removed by passing it through a solution of caustic soda. This method can be used to advantage only where manganese dioxide and muriatic acid (the essential chemicals for generating chlorine) can be obtained cheaply enough.

The production of oxygen from bleaching powder has at various times been the subject of attempts to adapt it to industrial requirements or to the requirements of the individual consumer of oxygen. A simple generator for that purpose had been proposed fifty years ago by Varrentrapp. An ordinary acid-carboy is partly filled with the chloride of lime mixture and is then closed up by a tight-fitting plug, having an exit pipe of sufficient width. This carboy—basket and all—is placed into a wash kettle or the like, and the water is heated to boiling. The contents of the carboy will yield 1000 to 1200 liters (35 to 43 cu. ft.) of oxygen. Fleitmann recommended the use of steam-jacketed boilers, where the gas can be obtained under a higher pressure and also in large quantities.

Jaubert recommends the following: 100 parts of the dry bleaching powder are mixed with 1000 parts of cold water and allowed to settle. The clear liquid is decanted into the generator. To this is added, while stirring, a concentrated solution of 8 parts of crystallized cobaltic chloride. The reaction is said to last five minutes, while it would take from 1 to 2 hours if but 2 parts of cobalt salt was used. The only objection that could be raised against this method would be the rather high cost of the catalytic substance.

It may also be mentioned that in most of these methods some of the calcium hypochlorite is liable to be transformed into the chlorate, which, of course, lessens the output of oxygen.



OXYGEN GENERATOR, USING BLEACHING POWDER.

Three pounds of bleaching powder titrating 35 per cent of active chlorine should yield about 2½ cu. ft. of gas.

In 1903 Geo. F. Jaubert succeeded in finding new and extremely active catalytic substances which were much cheaper than cobalt salts and which cause a rapid generation of oxygen even in the cold. Such substances are the sulphates of iron and copper when used in combination; if used alone the decomposition is an extremely slow one, even if heat is employed.

The proportions as proposed by Jaubert are 60 parts of dry bleaching powder mixed in a suitable vessel with 350 parts of water. This mixture is poured into the generator. To start the reaction a solution of 12 parts of sulphate of iron (or manganese) and 3 parts of sulphate of copper in 50 parts of water is slowly added, while stirring. It is probably better to mix the copper sulphate solution with the bleaching powder and add the iron salt solution when required.

Several welding shops in this country have adopted this or at least similar methods for producing oxygen. As a modification of this process the dry bleaching powder (220 lb.) may be mixed with dry sulphate of iron (33 lb.) and sulphate of copper (11 lb.). This powder evolves oxygen when placed in water. Epurite is a trade name for such a combination. The gas can be generated in an apparatus similar to calcium carbide generators. The generators should be provided with suitable stirring devices (paddles) and suitable apertures for introducing the chemicals and removing the residue. The exit tubing is connected with a scrubber to remove any impurities, and from these leads to the gas holder.

The accompanying sketch shows a generator of this kind, the invention of B. Artique (Brit. Pat. 14,848, of 1904). The apparatus is made of sheet iron, having a tight-closing cover 2. A perforated cylinder is placed inside the generator, the chloride of lime being introduced through a door 4. This cylinder can be rotated by means of a wheel 5. The agitator 6, having a handle 7, serves to stir up the deposit of calcium chloride. The solution of sulphates is contained in the reservoir 8, from where it passes into the generator by means of a funnel 9 and a pipe reaching below the water level. The gas evolved passes through the pipe 13 to the gas holder. Two such generators may be used alternately.

Where a larger supply of oxygen is required it would be preferable to use cast-iron generators, topped by a dome or a "gooseneck," to which is attached the exit pipe; or a lead-lined double-jacketed copper kettle may be used. Heating, although not necessary, hastens generation; the temperature should, however, not exceed 80 deg. C. The feed pipe for the solution of sulphates should reach more than half way down the "milk" of bleaching powder; it will then, at the same time, act as a safety pipe.

It may also be mentioned that the catalytic agent may be suspended in cylinders made of porous material which are immersed in the liquid. This modification had first been proposed by Jaubert, but a patent on a generator of this type has only recently been granted to M. Mauran and J. H. MacMahon (U. S. Pat. 1,001,873, Aug., 1911). In the latter case the metallic oxides are mixed with Portland cement or baked clay and are used in connection with "lavoisite."

The oxygen may also be produced under pressure, as the latter does not prevent decomposition of the bleaching powder. E. H. Kirkpatrick, who has experimented along these lines, found that evolution of oxygen takes place at a pressure of 10 and even 15 atmospheres (150 to 225 lb.).

If the dry bleaching powder is mixed with small quantities of slaked lime, and heated to redness, oxygen is also given off (H. Deville).

Bleaching powder has no dangerous properties, therefore large quantities may be stored. All the work connected with the generation of oxygen can be done by unskilled labor. The chloride of lime usually titrates 33 to 35 per cent of "available" chlorine. It is sold in barrels, drums or casks at about 1½c. per lb. The cost of oxygen does not exceed 2c. per cubic foot; this process, therefore, compares favorably with the chlorate process.[1]

It may be added that instead of bleaching powder any other alkali-hypochlorite may be used, or the solutions of these hypochlorites (Javelle water, Labarraque water).

Metallurgy of Molybdenum.

A recent publication of the Mines Branch, Department of Mines, Canada (Dr. Eugene Haanel, director), contains a report on the Molybdenum Ores of Canada, by Dr. T. L. Walker. While the greatest part of the bulletin is devoted to a review of the Canadian molybdenum deposits, there is also an interesting introductory chapter on some phases of the metallurgy of molybdenum from which the following information is taken.

The chief molybdenum ores are molybdenite MoS_2, molybdite MoO_3 and wulfenite $PbMoO_4$.

Concentration of Molybdenite.

According to Dr. Walker, the preparation of the crude ore for the market is one of the most difficult problems in ore dressing. Up to the present it is doubtful if a satisfactory solution has been arrived at. The mineral is very soft, and usually occurs in a very hard gangue, largely quartz and feldspar. In attempting to crush by stamps or rolls, much of the molybdenite is finely divided, so that a large loss results by sliming. On the other hand some of the larger flakes resist the action of the rolls, and may be separated by means of sieves. In density, molybdenite is heavy enough to separate readily by washing, were it not for its perfect cleavage giving rise to very thin scales and plates, which readily float away and are lost.

In general there are three methods of molybdenite concentration which may be applied after cobbing and hand picking

1. The ore may be crushed and concentrated by washing Mr. J. Walter Wells some years ago carried on experiments with this method of treatment in view. A brief report of the results of this work is given in the following extract from *Mineral Industry*, 1903, page 478.

"Experiments were carried out by Mr. Wells for the purpose of finding suitable methods for concentrating the Canadian ores. On a sample containing 50 per cent pyrrhotite, 10 per cent pyrite and 6.5 per cent molybdenite in a gangue of calcite, biotite, quartz and pyroxene, good results were obtained by crushing in a jaw crusher, hand picking of the large flakes of molybdenite, recrushing in rolls set to 0.2-in. space, and successive sizings in screens from 0.3-in. to 0.5-in. mesh. The oversize from the screens, which consisted of molybdenite, mica and rock, was treated on a Wilfley table and yielded a commercial product. The Hartz jig was not adapted for concentrating this ore, but good results were obtained with the Wetherill magnetic separator, although, owing to the high current and slow speed necessary, it is doubtful if this separation can be done on a practical basis. Treatment by a modified form of the Elmore process was only partially successful, as the large particles of molybdenite were not affected by the oil. Another sample consisting of quartz and feldspar with 2.5 per cent molybdenite, was crushed and sized, but gave no clean ore on any of the screens. The whole sample was then ground to pass an 0.05 screen, and concentrated on a Wilfley table; the final concentration being effected by the oil process. The experiments carried out by Mr. Wells showed that no standard method can be adopted for concentrating molybdenum ores. Separate tests are required to determine the proper treatment.

2. Crushing and dry concentration has been employed at Copper, Maine, where the ore is granite, containing fairly coarse foliated molybdenite. The history of the concentrating operation of the American Molybdenum Company is briefly told by Mr. Hess (Bull. 340, U. S. Geol. Surv.) as follows:

"The plant consisted of a 35-hp boiler and engine,, a Sturtevant jaw crusher and roll, and four sets of special rolls, each 3 ft. in diameter and 10 in. wide. The crusher was only a couple of feet above the floor, from which the material, crushed to about ¼-in. square, was elevated to the Sturtevant roll, 18 in. in diameter by 4 in. wide, which reduced the ore to about ⅛ in. It was then elevated to a bin at the top of the building, from which it fell to a series of two special rolls, thence it was elevated to a third special roll, and run through a 34-mesh screen. The molybdenite caught on the screen was delivered to a box at the end. The material going through the screen was carried by an elevator and screw conveyor to a fourth roll, from which it fell onto a 40-in. screen and from that to a 60-mesh screen. What went through the 60-mesh screen was elevated and sent to the tailings pile. It is readily seen that the repeated elevations of the material meant a considerable waste of power. The mill ran only six weeks, and it is said to have made about a ton of concentrates, a portion of which seen by the writer was very clean. In the tailings some fine flakes of molybdenite were found, but the amount seemed small. Such a process, if mechanically perfected, might work profitably on deposits where, as in this one, the molybdenite flakes are comparatively broad, but would be wholly unsuited to deposits like many of those in Colorado and elsewhere, in which the individual flakes are of almost microscopic size."

3. A process apparently well suited to molybdenite ores has been recently brought forward by F. E. Elmore. The Elmore flotation process was described in an illustrated article in our

[1] See the article in this journal, Vol. IX, page 641 (December, 1911).

Vol. VI, page 187 (1908). Its essential features are the use of oil to float the metallic particles and the employment of a partial vacuum.

At the testing plant of the manufacturers of the Elmore flotation apparatus in London three tests on concentrating molybdenite resulted as follows:

Sample Number.	Nature of Gangue.	P. C. Molybdenum In Ore.	In Tailings.	In Concentrates.	P. C. Saved.
1	Feldspar	3.40	0.25	40.80	93.2
2	Much garnet and magnetite	2.30	0.06	51.57	98.1
3	Not stated	5.21	0.17	54.7	97.0

A sample of the ore from the claims of the St. Maurice Syndicate, Lake Kewagama, was treated by this process by the Denver Engineering Works Company, of Denver, Col. The sample was small, but the concentration was very satisfactory, with a minimum loss in the tailings as illustrated by the following report:

"Following are the results obtained by the Elmore process on the sample of molybdenite submitted my Mr. J. C. Gwillim. The mineral seemed free at 16 mesh, but owing to the small diameter of the delivery tube of the laboratory machine it was found necessary to crush it finer before making the test.

"Five hundred grains of ore assaying 1.70 per cent molybdenum were agitated four minutes with 5 c.c. acid, 2 c.c. Beaumont oil, then four minutes with 5 c.c. acid and 1 c.c. oil; 2.5 c.c. acid were used for gas, and test was under vacuum 2.25 minutes. The following products were obtained:

20 grains concentrates.....42.90 per cent molybdenum
472 grains tailings.....trace

"This gives the ratio of concentration of 25 tons into one and a recovery of 100 per cent. The recovery of figures are slightly in excess of 100 per cent, owing probably to discrepancy of a few hundredths in crude assay. The tails showed acid reaction and were quite clean.

"The amounts of acid and oil used could probably be lowered very materially, but owing to the lack of time and urgent requests to rush the work these investigations were not undertaken."

At the Great Knaben mine, in southwestern Norway, which has produced from 25 to 30 tons of molybdenite annually since 1902, water concentration with jigs and tables has been abandoned, and more satisfactory results are said to have been obtained by the use of the Elmore oil concentration. The ore is first cobbed, and the poorer ore sent to be concentrated.

In 1899 Professor J. B. Porter, of McGill University, made some experiments on the concentration of molybdenite for the Geological Survey. From the two samples examined he concluded that the most satisfactory method was cobbing and hand-picking.

The following extract from the Report of the Geological Survey of Canada gives the main results of Professor Porter's investigations. (Report of the Geological Survey of Canada, Vol. 13, page 10, 1900.)

"The first, or Egan Township sample, weighing 289 pounds, and containing in all 15.92 per cent of molybdenite, was cobbed and hand-picked in the Survey, yielding 39 lbs. of clean mineral in crystalline flakes. The remaining 250 lbs. of the cobbed ore was then sent to Professor Porter, who ascertained that it still contained 2.8 per cent of molybdenite. By a dry process of rolling and screening, followed by jigging, nearly all the molybdenite was extracted from this ore, in a series of concentrates ranging from 70 per cent to 15 per cent molybdenite. It is not necessary to refer to the details of treatment here, but the results appear to show that in the case of molybdenite ore of this class, in which the crystalline masses are of considerable size, it would not be economically possible to employ any crushing and concentrating process. The problem resolves itself into one of cobbing and hand-picking at remunerative rates. The associated minerals in this case were: pyroxene, iron pyrites and mica.

"The second, or Ross Township sample, weighed 250 lbs. The gangue was chiefly quartz, and, although the molybdenite made a considerable showing, it was found by Professor Porter to amount to only about 1 per cent. This specimen was not cobbed or hand-picked. By concentration it was determined that about 52 per cent of the molybdenite could be saved in the form of a concentrate containing 33.50 per cent of the mineral. The grade of this concentrate appears, however, to be too low for present commercial requirements."

It is worthy of note that none of these processes has up to the present been employed very satisfactorily for the separation of molybdenite. It would seem as if a reasonable combination of the dry screening process for the removal of the coarser flakes, followed by a treatment of the tailings by the vacuum process, should give results superior to those obtainable from the employment of any one of these methods alone.

In New South Wales and Queensland, which produce a large part of the world's molybdenum ores, the molybdenite-bearing quartz is hand-picked, crushed through rolls, and then jigged. The oversize is recrushed, hand-picked again, and finally treated on Wilfley tables. (Mineral Industry, 1907, page 722.)

For the market the ore should be concentrated to about 90 per cent molybdenite, for which, at present, the current rate is about $550 per ton. The market rate, however, is very variable. The presence of even small quantities of copper, arsenic or bismuth, may render the ore less suitable, particularly for steel manufacture.

Uses of Molybdenum.

Until recently molybdenum was required only for the manufacture of chemical preparations, principally ammonium molybdate, which is much used in the determination of phosphoric acid. The iron and steel works of the United States alone are said to consume as a chemical reagent several tons of molybdenum annually.

Molybdic acid is used as a blue pigment in the manufacture of porcelain, and for dyeing silks and woolens. In various compounds molybdenum is used for coloring leather and rubber.

Ammonium molybdate is used for fireproofing, also as a disinfectant for cloth used in railway passenger carriages.

The chief use to which most of the world's molybdenum is put is in form of ferro-molybdenum, the preparation of special varieties of steel. The result of the addition of a small portion of metallic molybdenum to steel is very similar to that obtained by the use of tungsten. Molybdenum is more potent than tungsten, and only about half as much of the molybdenum is necessary as would be required were tungsten used instead.

Molybdenum steel is used for rifle barrels, propeller shafts, large guns, wire, and particularly for the manufacture of high-speed tools. Molybdenum high-speed steel contains from 8 to 10 per cent molybdenum. When the other elements are present in the right proportion a steel is obtained of great hardness, with the peculiar property of retaining its temper when heated to a high degree, differing in this respect from all carbon steels. Owing to this property it is possible to take extremely heavy cuts at high speed, the tool often being heated through this hard use to a dull red heat without impairing its usefulness.

To prevent the freezing of concentrates which form one of the components of the mixture treated on Dwight-Lloyd sintering machines, a steam-heated covered bin is in use at the Salida plant of the Ohio & Colorado S. & R. Company. The walls of the bin are double and filled with coke. Both entrances are provided with two sets of doors, and a temperature well above the freezing point is easily maintained by the heat from two steam pipes which extend along each side of the bin near the roof. The scheme has proved very successful, and involves little expense other than cost of construction.

Metallurgy in British Columbia.

By E. Jacobs.

The chronology of metallurgy in British Columbia in 1911 records only a few items of progress and achievement. The Dwight-Lloyd system of sinter-roasting was installed at the Trail smelter of the Consolidated Mining & Smelting Company of Canada, as recorded and described in Metallurgical and Chemical Engineering in August, 1911, page 405. Later information is to the effect that the plant is successfully roasting copper concentrates, but that similar success has not resulted in treating lead-zinc ores, the latter frequently requiring a second treatment.

The Elmore oil-vacuum process was experimented with at the copper concentrator of the Britannia Mining and Smelting Co. Graded crushing and concentrating had been developed to a very satisfactory point at this plant, resulting in a recovery of 80 per cent, due largely to hand-sorting and coarse jigging. Loss in slime, however, had been excessive, and it was in an effort to overcome this loss that the Elmore process was tried. The results obtained from a standard-size unit show a high recovery from fine ore and slime, which will materially increase the present total recovery of 80 per cent. The product will be nearly neutral as far as smelting is concerned.

The French Zinc Process.

Mr. A. Gordon French, a metallurgical chemist who has previously experimented with the reduction of lead-zinc ores at Nelson, B. C., has patented a process which is designed to extract and recover the zinc from such ores as the lead-zinc ores of the Slocan district, British Columbia, leaving a residue containing the silver, lead, iron and gangue to be smelted as a lead ore free from zinc. The advantages claimed for the process are:

1. The recovery of zinc in metallic form.

2. By the removal of the zinc from the original ore, the residue becomes more desirable as a smelting ore, and is higher in grade by reason of the concentration caused by the removal of the zinc.

3. The silver actually occurring in the blende would remain in the residue and be recovered by smelting, whereas it would be lost if the blende were to be removed from the ore mechanically.

The ores experimented on have been concentrates containing galena, blende, pyrite, iron carbonate, gangue and a small percentage of manganese. The ore is crushed to 10-mesh size and roasted to a "dead" roast, converting the sulphides to oxides and some sulphate. While the roasted ore is still in the furnace, a small percentage of nitre-cake is added and thoroughly mixed, being still subjected to the heat of the furnace. The oxides are thus almost completely converted to sulphates.

When the mass has cooled it is leached with water to which some nitre-cake has been added, and the sulphates of zinc and manganese dissolved, together with sulphate of soda. The sulphate of lead is not soluble, and the silver can be rendered insoluble, both remaining with the gangue in the tank. It is claimed by the inventor that sulphate of iron is not dissolved until all the zinc is in solution, and that if the leaching is stopped before the zinc is entirely dissolved no iron will appear in solution.

The filtrate, containing sulphates of zinc, manganese and soda, is then electrolyzed by a direct-current of low voltage, using lead anodes and zinc-sheet cathodes. Zinc is deposited on the cathodes until the desired thickness is attained, when the sheets are removed and stripped, and the zinc melted into bars. Manganese precipitates on the anode as the black oxide, which is brushed off occasionally and accumulates in the bottom of the tank. In practice the circulation of the electrolyte through the leaching tank and electrolytic cell is continuous.

The experimental plant at Nelson has a capacity of only 500 to 1000 pounds of ore. It consists of a roasting furnace with a hearth area of [illegible] by 20 ft., a leaching tank, electrolytic cell, and two solution storage tanks. The upper 15 ft. of the roaster hearth is inclined at an angle of 10 deg., the lower 5 ft. being level.

Stamp Milling and Cyaniding.

The Hedley Gold Mining Co. mines and mills an auriferous arsenopyrite, in which gold is practically the only metal of value. During 1911 the mill treated approximately 57,000 tons of ore of an average value of $12.10 per ton, recovering 92 per cent, or $11.13 per ton. This estimate may be altered slightly by the official figures, but is approximately correct. In comparison with the preceding year the recovery for 1911 was 4 cents per ton higher.

The system of treatment is as follows: The ore is crushed through 14-mesh screen by forty 1050-pound stamps dropping 7¼ inches, 99 times per minute. No gold is recovered by amalgamation, and the pulp is immediately sized through Bunker Hill screens fitted with 60-mesh wire cloth. The screen oversize is concentrated on corrugated-belt Frue vanners, the vanner tailings being reground in a Gates tube mill fitted with Montana-Tonopah lining. The screen undersize is combined with the tube mill product, and the whole is then classsified into sand and slime. The sand is concentrated on smooth-belt vanners and the slime on Deister slime tables. All concentrates, amounting to about 300 tons per month, are sent to the smelter at Tacoma, Wash.

The sand and slime tailings are separately treated by cyanidation. The sand, which is all finer than 60 mesh, is leached for 20 days. The slime is mechanically agitated and allowed to settle. As much clear solution as possible is decanted, and the residue filtered in Oliver filters. The combined gold solutions from leaching and filtering are then precipitated by zinc dust in two Merrill presses, standard 36-in. frame, with 20 and 10 leaves, respectively.

The Motherlode Sheep Creek Mining Co. has recently constructed a 10-stamp cyanide mill, which was expected to be in operation about the first of this year. The best talent available has been employed in designing this mill, with a view to making it thoroughly representative of modern cyanide practice. The mill building is 187 ft. long by 87 ft. wide. The stamps weigh 1250 lbs. each. After crushing, the pulp will be classified in cones, the underflow being reground in a tube mill to pass a 200-mesh screen. The classifier overflow will be combined with the tube mill product, and passed over silver-plated amalgamating plates. Following this the pulp will be thickened in Dorr thickeners, the clear overflow being returned to the battery storage tank. The thickened pulp will be agitated in Pachuca tanks with cyanide solution, again thickened in a Dorr thickener and finally filtered in Merrill slime presses. The cyanide solutions from the Dorr thickener and Merrill presses will be clarified, precipitated with zinc dust and passed through a Merrill precipitating press having a capacity for one month's run.

The gold precipitate will be dried, ground, fluxed with soda, borax and litharge, briquetted, and cupelled to high-grade bullion. Amalgam from the plates will be retorted and melted in the usual manner.

The mill is to be operated by water power. Water from two creeks is conducted through red fir pipe lines, 2100 and 4500 ft. long, respectively, and thence through one 7000-ft. steel pipe line, graded from 16 to 14 inches. The effective head at the mill is 600 ft.

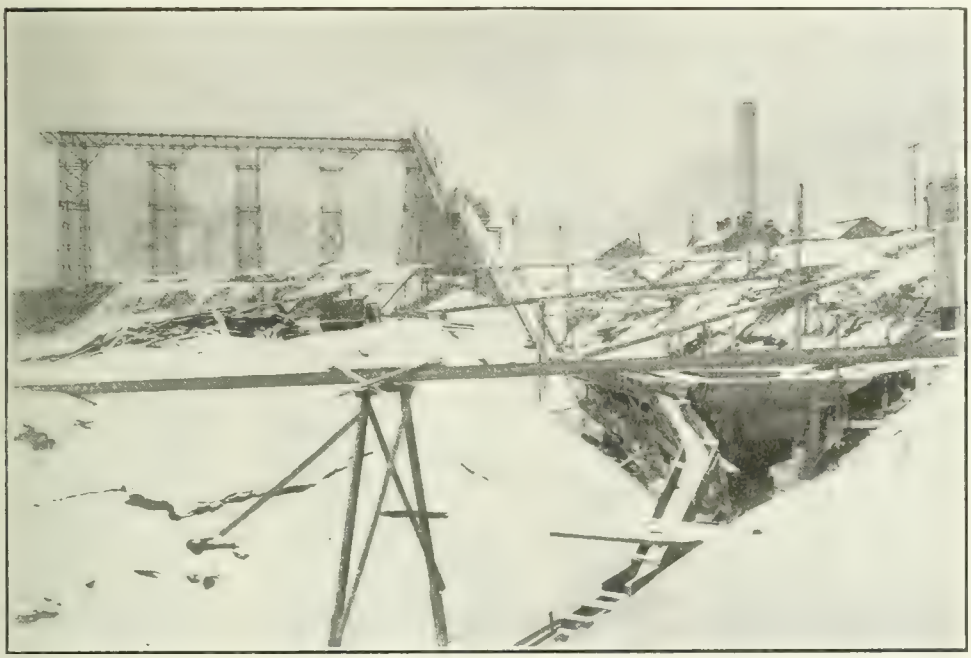
Copper Smelting.

In his last annual report for the fiscal year ended June 30, 1911, Mr. Jay P. Graves, vice-president of the Granby Consolidated M. S. & P. Co., made the following reference to cost of mining and smelting: "Notwithstanding the lower tonnage shipped and the disadvantages under which it was mined by starting and closing the mines at various periods, the cost of mining was only one cent per ton greater than in the previous

year, while the cost of smelting was reduced three cents per ton. I consider this most excellent work in view of the conditions which prevailed at both mines and smelter. I believe it safe to say that the conditions at the mines and smelter are now such that when we are able to operate at full capacity much better results will be achieved and lower costs secured." The tonnage for the fiscal years referred to by Mr. Graves was 950,503 tons for last year, and 1,175,548 tons for the year preceding. The lower costs applied to a tonnage reduced in quantity by 19 per cent.

Conditions during the greater part of the calendar year 1911 were unfavorable to economical work, for a strike of coal mine employees cut off the local supply of coke; and although coke was imported from Pennsylvania for a time, the cost was prohibitory in smelting the characteristic low-grade ores from the mines of the Granby company. As a result, operations have been suspended until local supplies of coke are again available. The labor trouble had a disastrous effect on the production of copper by the Granby, the output for the year being only 11,000,000 lbs. as compared with 20,000,000 in 1910.

The British Columbia Copper Co. operated its mines and smelter throughout the year, notwithstanding the serious disadvantage of the high cost of Pennsylvania coke. The tonnage of ore smelted at Greenwood was about 580,000 tons, from which was recovered 29,600 oz. gold, 127,000 oz. silver, and 9,650,000 lb. copper. Compared with 1910 these figures show an increase in tonnage smelted of 27 per cent, and in copper produced of 31 per cent. The cost of smelting this year will be higher than usual, and will not compare favorably with the cost in former years. The cost of producing and marketing refined copper, after crediting the value of gold and silver recovered, has formerly been as follows: For the fiscal year ended November 30, 1908, 9.996 cents; 1909, 9.829 cents; 1910, 9.048 cents. Further reductions may be expected in 1912 if conditions continue normal.



SLAG DISPOSAL AT GRANBY SMELTER, GRAND FORKS.

New Slag Disposal System.

The excessive cost of continuing the hot-slag haulage system at the Granby smelter at Grand Forks has caused the management to devise new means of slag disposal. The general plan was described in METALLURGICAL AND CHEMICAL ENGINEERING, August, 1911, page 405, but the scheme will be better understood by reference to the accompanying photograph.

Central storage bins have been built below the level of the present slag dump, and to these the granulated slag will be sluiced in flumes. After having been dewatered the slag will be conveyed by belt up an inclined trestle, and discharged by a movable distributor. The space under the incline will be filled first, and later the level trestle will be used as a dumping point. An extension belt can be used for dumping beyond the end of the level trestle when the ground beneath it is filled. It is expected that the system will provide for the disposal of from six to ten million tons of slag, and if its operation proves successful all of the slag from eight blast furnaces will be disposed of in this way.

The Magnetic Properities of Some Nickel Steels

Messrs. E. Colver-Glauert and Seigfried Hilpert (*Journal*, Iron and Steel Inst., 1911, pages 375-411) have investigated alloys of iron with 5.86, 24.32 and 32.9 per cent of nickel by a magnetometric method after slowly cooling from 1250° C., after quenching from 1240° C., 900° C. and 600° C., and after cooling to —50° C., —100° C. and —180° C. The 5 per cent steel is not affected by quenching from 600° nor by cooling, but by quenching from 900° is rendered martensitic and has its coercive force considerably augmented; when quenched from 1240° it becomes only partly martensitic and magnetically softer. The 25 per cent steel is non-magnetic under stable conditions, but at low temperature becomes magnetic without exhibition of any definite critical point; and when quenched at 1240° is equally magnetic at —180° as when slowly cooled. The authors suggest that at high temperatures there may be formation of a highly magnetic substance dissociating between 900° and 600°, but reforming on further slow cooling. When quenched from 600° the structure is similar to that of natural meteoric irons, and at low temperatures approximates to that of quenched high-carbon steels. The 33 per cent steel is but slightly affected by quenching, and undergoes no change when cooled below 0° C. It has a polyhedral structure, but etching with sulphurous acid brings out an apparently duplex structure similar to that of the 25 per cent steel.

Steel Pipe Contract.—Messrs. J. G. White & Company, Inc., of New York and San Francisco, have just purchased 124 miles of 12-in. steel pipe to be used by them in building a natural-gas line for the Midway Gas Company in California. The pipe will weigh approximately 11,000 tons, and with transportation, will cost approximately $600,000. The particularly interesting feature of his contract is that quotations were asked from British, German and French manufacturers, and the best foreign price was that of a British firm, which, exclusive of duty and freight, was approximately double that at which the contract was placed with the National Tube Company, a subsidiary of the United States Steel Corporation. This indicates the remarkable resources of the United States for cheap production of steel.

The American Museum of Safety has awarded the Travelers' Insurance Medal to the Pennsylvania Railroad Company, the Scientific American Medal to the Norton Company, and the Seaman Medal to Dr. Doty.

Recent Improvements in Filtration Methods*

By Ernest J. Sweetland.

Probably the simplest method of filtration is that of pouring the liquid to be filtered into a suspended bag and catching the solid matter in the bag while the filtrate is caught in a receptacle below. This method was conceived in the kitchen and has been used by housewives for generations. Although it seems primitive, it is the method at present employed in most cane sugar refineries. The great disadvantage of bag filtration is that the bags have to be turned inside out to be cleaned.

The method of filtering through bags inwardly, that is, passing the liquid from the outside of the bag and draining the filtrate from the interior, has also been employed in sugar-house work to a limited extent. By this method the solids are deposited on the outside of the bag, and it is, therefore, more easily cleaned. In this type the usual arrangement is to enclose a corrugated plate or grid in the flattened bag to prevent it collapsing under external pressure, and a series of bags so arranged are enclosed in a box capable of sustaining a moderate pressure.

A flat filter bag provided with means to prevent it from collapsing when subjected to external pressure, and having a suitable drainage outlet for filtered liquor, constitutes a filter leaf. The different methods by which filter leaves may be constructed are too numerous to be described in detail here.[1]

The first large leaf filter installations were introduced in the cyanide process, and were of the vacuum type.

In the vacuum leaf-filter the leaves are arranged in groups and submerged in the liquid to be filtered, and suction applied to the interior of the leaves. The partial vacuum formed draws the filtrate into the leaves, whence it drains to the vacuum receiver, or, in the absence of a receiver, it is drawn directly through the vacuum pump.

Vacuum leaf-filters are divided into two classes: namely, the movable leaf type and the stationary leaf type. In the former (Fig. 1) the "cake" of residue is first deposited on the surface of the leaf to a thickness of one-half to three-quarters of an inch. The sludge[2] is then withdrawn from the filter box, and wash water is admitted to take its place. During the time the change from sludge to wash water is taking place vacuum is maintained in the leaves to prevent the cakes from dropping off. The cakes will not fall as long as the vacuum is continued. As soon as the leaves are submerged in the wash water, washing commences, and is continued until the valuable solution in the cake has been displaced with water. When this is done the suction is discontinued.

The next step is to dislodge the cakes from the filter leaves and discharge them. This is done by simply admitting compressed air into the leaves, which bulges the cloth slightly and the cakes immediately fall to the bottom of the hopper.

When the cakes have fallen the surplus water in the box is decanted off for re-use, and the pasty mass of cake is discharged through a large valve at the bottom of the hopper.

The operation of the movable leaf type is similar to that of the stationary type, except that, instead of the sludge and wash water being transferred, the group of leaves is transferred by a travelling crane from a sludge tank to a wash water tank.

The requirements of a filter in the cyanide process are most exacting. When it is noted that a moderate-sized plant will handle 300 or 400 tons of ore residue, or slime, per 24 hours; that the cost of filtering must be well under 10 cents per ton of dry ore filtered, and that the element in solution to be recovered by washing is in many cases gold, worth $20.67 per ounce, the importance of the filter is realized.

In the case of a cyanide filter working on a gold ore, in good practice the amount of dissolved gold which escapes recovery will range from one two-hundredth to one five-hundredth, or an ounce per ton of dry residue, or say about one grain per ton.

This splendid washing efficiency is due to what I shall take the liberty of calling "direct-contact washing." The cake is deposited in an even layer on the leaf, and, when submerged, is in direct contact with the wash water. The cake has been deposited in a natural unrestricted manner without packing or crowding, and with an even pressure in all directions. A cake deposited in this manner will, if all conditions are suited to the material in hand, be of even thickness throughout and of even density, but if during the cake-forming some disturbing influence enters, which tends to cause the cake to vary in thickness, the density, or perviousness, of the cake will automatically adjust itself to suit the varying conditions, which insures even washing.

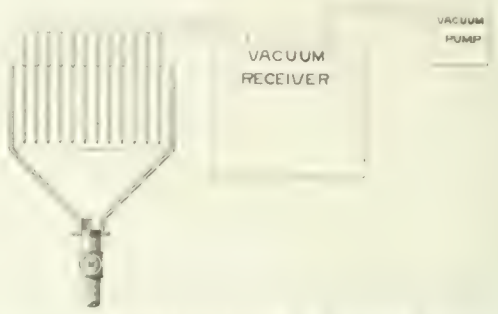


FIG. 1.—MOVABLE LEAF TYPE OF VACUUM FILTER.

The rate of percolation through the cake is governed by the resistance offered by the cake and the pressure of the liquid against the cake.

Other conditions being equal, two cakes of the same thickness and of the same degree of porosity will offer equal resistance to percolation, and therefore filter at equal rates per unit of area.

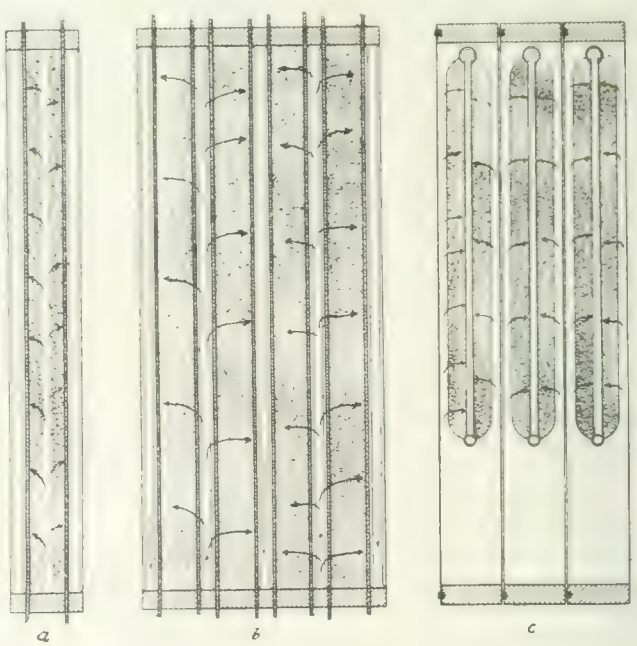

FIG. 2.—PLATE AND FRAME FILTER PRESS.

If two cakes vary in resistance they must vary in thickness in order to be equally washed in a given time.

To properly consider these statements it is necessary to consider the resistance of the filter cloth as well as that of the cake. That is, the resistance per square foot of cake is equal to the resistance of 1 sq. ft. of cake plus the resistance of the square foot of cloth underlying it.

*Presented at the Meeting of the American Chemical Society, New York, Jan. 5, 1912.

[1]Several small leaves of simple construction were exhibited at the meeting for examination.

[2]The term "sludge" as here used means a fluid mixture of liquid and solid matter to be filtered.

For example, suppose that for some reason a portion of the cloth of a filter leaf has become partially obstructed and offers more resistance than the rest of the leaf. While cake forming is in progress the cake formed on this partially obstructed spot will be thinner than that in other places. Now when the cake is submerged in wash water the resistance which limited the thickness of the cake in this spot again comes into play and limits the amount of wash water which passes through it. In this manner the thin cake receives an amount of wash water proportionate in its volume.

Before proceeding let us compare the cake forming and washing in a common plate and frame filter press with the

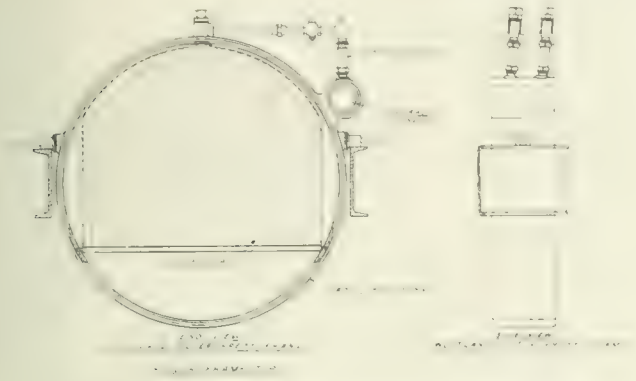

FIG. 3.—DETAILS OF SWEETLAND FILTER PRESS FRAME.

same in leaf filters. In forming a filter cake with any material there is a certain point where the rate of filtration begins to drop off very rapidly due to the resistance offered by the cake. When this decrease has been noted, the cake has reached the economical limit of thickness, and to proceed farther is a waste of time and power. For instance, it has been noted that with certain colloidal materials a cake of ½ in. can be formed in about 30 minutes, but at this point filtration becomes so slow that to increase this cake to 1 in. in thickness would take several hours. Obviously this would not be economical.

In a plate and frame press each wall of the frame cell is a filtering wall, and the cake builds up on each wall until the two adjacent cakes finally join together to form a single cake filling the entire cell. In Fig. 2, *"a"* shows the cake partly formed, and the arrows indicate flow in both directions while filling the press. In *"b"* the cells are shown filled, the arrows indicating direction of flow of wash water; *"c"* shows cakes on filter leaves and the arrows indicate the direction of flow both while cake forming and washing.

Now to get the maximum cake-forming capacity from the filter press, the cake formed on each cloth must be up to the economical limit of thickness. This is all right if washing is not contemplated: but if the cake is to be washed we find that wash water has to be forced through a cake twice as thick as it should be.

If to overcome this objection the thickness of frame be reduced to give a cake of proper thickness for washing, then the capacity of the filter press for cake forming is greatly reduced. In all cases the frame must be solidly filled with cake, as otherwise the line of junction between the cakes formed on opposite surfaces of the cell will be soft and make good washing impossible. Furthermore, if the solid matter in hand varies in structure, some of it being granular while the rest is colloidal, the granular particles will tend to settle to the bottom of the filter press frames, making the lower portion of the cake more porous than the upper portion, and when washing is in progress the bulk of the wash water passes through the lower portion of the cake, leaving the upper part imperfectly washed.

Again, some cakes tend to shrink during washing, and shrink away from the rigid walls of the frames, leaving channels through which a portion of the wash water passes, unduly increasing the volume of wash water, and impairing the efficiency of the wash.

In leaf filters the maximum economical thickness of cake can be formed, because the cake is washed exactly as it was formed, a double thickness of cake never has to be washed. Then too, in the leaf filter, the direction of flow during washing is the same as during cake forming, while in the plate and frame press one-half of the cake is washed in the opposite direction to which it was formed against the grain, so to speak, and this tends to disturb the natural arrangement of the particles.

If the texture of the cake-forming material in which a filter leaf is operating varies, and the granular portion settles toward the bottom, the thickness of the cake will vary, and it will be thicker at the bottom than at the top, so that the granular portion which admits of the more rapid passage of wash water is thicker than the less porous portion, and really *requires* more washing.

What are technically known as vacuum filters are, in reality, pressure filters, operated by atmospheric pressure. Obviously in an open filter of this type the maximum pressure that can be brought to bear under ideal conditions would be 14.7 lb. per

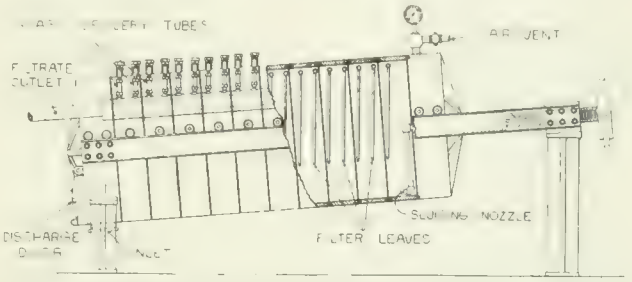

FIG. 4.—SWEETLAND FILTER PRESS SHOWN PARTIALLY IN SECTION.

square inch. Under practical conditions the vacuum maintained is usually about 22 in. or the equivalent of 11 lb. pressure per square inch. Since the rate of filtration is in proportion to the pressure, the low pressure available in vacuum filtration makes the size of installation necessary for a given capacity very large. This gives rise to a number of objections, namely:

Large initial cost.
Large floor space and head room required.
Excessive power consumption.
High cost of maintenance.

In addition to these, vacuum filters are entirely unavailable for filtering hot solutions.

The logical means of overcoming the objections cited is to enclose the filter leaves in a chamber so that greater pressure can be used and thus greatly reduce the size of the installation, since the principles governing leaf filtration apply regardless of whether suction or external pressure is used.

The difference betwen vacuum and pressure filters has been aptly explained by saying that in the former the liquid is pulled through the cloth while in the latter it is pushed through.

The number of mechanical arrangements by which pressure leaf filters may be constructed are many. Of these, three different types have been in operation on a large scale for some time. There are the Kelly, the Burt, and the Sweetland filters.

The Kelly filter comprises a plurality of leaves mounted on the door of a steel shell and provided with rollers by means of which the groups of leaves may be rolled into the steel shell and the door bolted in place. When ready for discharge the door is unfastened and the leaves rolled out of the shell.

The Burt filter comprises an inclined steel shell with vertical leaves suspended at intervals throughout the length of the shell. The cakes are discharged through a door in the lower end of the shell.

In designing the Sweetland filter I endeavored to keep in

view the great importance of easy accessibility of all the parts for examination or renewal, and at the same time to provide a construction of such flexibility as to meet the many and varied demands of the chemical and metallurgical industries. In general appearance the Sweetland filter somewhat resembles the standard types of plate and frame filter press, that is, it comprises a series of frames resting upon a pair of side bars, and an end piece, or head, forms a closure for each end. Each frame carries an inserted gasket of rubber or other suitable material, and the frames are clamped together to form a watertight chamber by means of a heavy screw bearing against the movable head.

Each frame carries a removable leaf, and in the usual construction a space is left between the bottom of the leaf and the lower wall of the frame.

The operation is as follows: The liquid to be filtered is admitted to the chamber through an inlet at the bottom; while filling, the enclosed air escapes through a valve at the top. When the air escape valve is closed the pressure increases within the chamber and filtration begins. When the cake has formed to a suitable thickness the source of supply is shut off and the excess unfiltered liquid is withdrawn from the chamber.

FIG. 5.—SECTION OF LEAD-LINED FILTER.

In most cases the cake will adhere to the leaf without assistance, but in case the material in hand shows a tendency to drop off the leaves the cakes are held in place by vacuum applied to the interior of the leaves. The excess sludge having been removed, wash water is admitted to the chamber under pressure, the enclosed air being allowed to escape as before. The wash water percolates through the cakes and displaces the soluble salts. This done the excess wash water is withdrawn for future use.

The cakes are now to be discharged. If wet discharging is permissible, water under pressure is turned through the discharge nozzles at the upper end of the press. The cakes are then forced off of the filter leaves with compressed air, and as they fall to the bottom they are rapidly sluiced out through the discharge door in the lower head of the press.

If it is desired to remove the cakes as dry as possible, they are caused to drop into a tray which is inserted into the space in the bottom of the press, or else they are allowed to drop into the space below the leaves and are removed with a hoe or scraper.

If the Sweetland filter is used to clarify a solution containing but a small percentage of solids, the space in the bottom of the press offers a material advantage, for in this space accumulated solids may be stored without obstruction to the filter surface. When the press is in operation in this manner it is allowed to run until accumulated solids on the leaves begin to materially decrease the rate of flow. When this occurs a puff of compressed air is admitted to the interior of the leaves, and the rush of air through the pores of the cloth in the contrary direction to filtration disengages the solids from the filter cloth, and the thin cakes fall to the bottom of the press, to lie there until sufficient has accumulated to justify opening the discharge door and flushing out the press.

The sectional construction described permits of a great many modifications. Lead lined presses of this type have been built for acid solutions, the sheet lead lining being joined by fusion to lead rings which are cast into the edges of the cast iron frames. (Fig. 5.)

The frames are made of wood for such materials as make the use of metal impracticable, and in such presses the head pieces are made of cast iron with wooden linings, and a wooden tray may be used to receive the cakes when discharging. (Fig. 6.)

Bronze presses of the Sweetland type are built, and have the particular advantage of being much lighter than plate and frame presses, since the filter leaf takes the place of the heavy plate.

These presses have also been built with steam spaces in the frames for maintaining the heat of the liquor being filtered. These spaces do not in any way interfere with the sectional construction.

The possibilities of leaf filtration are broadening every day. It has recently been demonstrated that, in refining oils and fats with Fuller's earth, the amount of oil left in the residue can be greatly reduced by the construction described, which means a notable saving.

The time is near at hand when bag filters in cane sugar refineries will be displaced by leaf filters of the pressure type,

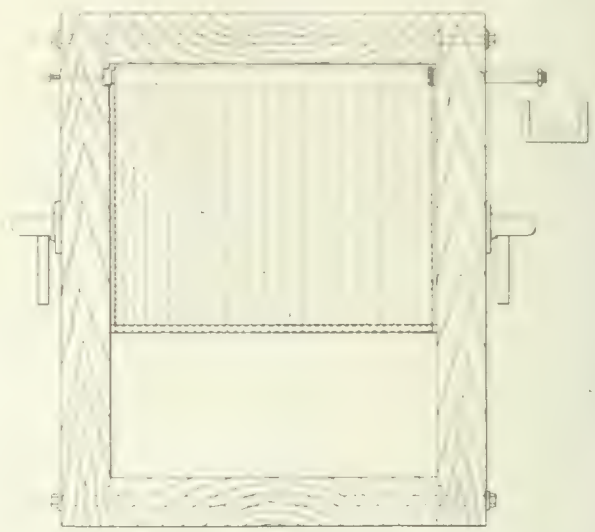

FIG. 6.—WOOD FILTER PRESS FRAME.

for not only is cleaning of the leaves made almost automatic by reversal of current through the cloth, coupled with suitable spraying devices, but the filter area required for a given capacity will be greatly reduced.

Experience has shown that filter cloth made into leaves lasts longer than the same cloth used in plate and frame presses, because on the latter the cloth is subject to handling, scraping and other mechanical injury from being squeezed between the units of the filter press.

The filtering requirements of the chemical industry are so many and varied that it would be absurd to blindly advocate any specific construction as a cure for all filtering evils. Each problem must be approached with care and each installation properly designed to suit the needs of the material in hand, and when this is done higher efficiency and lower filtration costs will be realized.[3]

The Granby copper smelter at Grand Forks, B. C., has resumed operations after a suspension of several months due to labor troubles at the coal mines. Coke was imported from Pennsylvania for a time, but this proved too costly, and operations were suspended until normal labor conditions were obtained in the province.

[3] All important features of the Sweetland Filter Press are protected by a series of patents owned by the Sweetland Filter Press Company, New York.

Recent Metallurgical Patents

Gold and Silver.

Clancy Process of Treating Gold Ores.—Mr. John C. CLANCY, of New York, has added another to his long list of recent patents for the treatment of gold ores by the use of amide compounds. In the present instance Mr. Clancy states that electrolysis can be dispensed with, and that an amidine compound, such as calcium cyanimide, forms with a cyanogen-bearing solution an active solvent for the precious metals. Alkaline ferro or ferrocyanides, soluble prussian or insoluble prussiates, are included in the list of cyanogen-bearing compounds which act thus with calcium cyanimide. The process is applicable to the treatment of old dumps from former cyanide treatment, for in these accumulations there exists a large proportion of Prussian blue, which when treated with alkali becomes substantially alkaline ferro or ferricyanide, or soluble prussiates. Low-grade ores also are amenable to this process, for it makes use of cheap materials.

For use on old-dump material Mr. Clancy gives the following procedure: 2000 lb. of water containing 1 lb. of cyanimide and 1 to 5 lb. of lime give results equivalent to the use of straight cyanide solution when used in the proportion of two or three parts of solution to one part of ore.

On low-grade ore the solution is made up as follows: 2000 lb. of water, 1 lb. of alkaline ferrocyanide and 1 lb. of lime. The proportions of solution to ore are the same as indicated above, and the time of extraction is eight to ten hours.

Zinc and Lead.

Treatment of Complex Ores.—Among those investigators who have given attention to the chemical treatment of mixed sulphide ores, Mr. EDGAR A. ASHCROFT, of Sogn, Norway, is well known for his proposed chlorination methods. Recently four interesting patents have been granted to Mr. Ashcroft, based on improvements in the treatment of mixed lead-zinc ores or concentrates.

The two principal products obtained from concentrating mills are (*a*) zinc concentrates containing upward of 40 per cent zinc, under 12 per cent lead and some silver; and (*b*) lead concentrates containing upward of 50 per cent lead, under 12 per cent zinc and some silver. In smaller quantities there is produced an intermediate product (*c*) such as slimes and middlings of varying composition. Zinc and lead smelting are respectively used for the reduction of these zinc and lead concentrates, but in the smelting processes the metals unfavorable to each are either wholly lost or imperfectly recovered at further expense. The product (*c*) is smelted only in small admixtures to the main products, or further separated into products resembling either (*a*) or (*b*). Mr. Ashcroft's patents refer, first, to the special treatment of (*a*) for the removal of the lead; second, to the treatment of (*b*) for the removal of the lead; and, third, to the treatment of the zinc residue from (*a*) and (*b*) for the recovery of the zinc.

The steps in the removal of lead and silver from zinc concentrate (product *a*) are briefly, as follows: Treatment of the crude concentrate with fused chloride of zinc (or preferably a mixture of the chlorides of zinc and sodium in molecular proportions, on account of the lower specific gravity and greater stability of this mixture), whereby reactions occur between the sulphides of lead, silver, antimony, iron, and manganese, and the zinc chloride, forming chlorides of the metals named and sulphide of zinc. The chlorides are then removed from the zinc sulphide residue, which is washed to remove any remaining soluble chlorides. The melt containing the lead and other metals is then treated for the regeneration of zinc chloride and the recovery of the metals.

Fig. 1 shows one method of carrying the invention into effect. The treatment is carried out at a temperature under 500 deg. C., in kettles *A* mounted on trunnions *B* and provided with an agitating apparatus B^1, and loops *C* whereby the pots can be lifted by cranes. Each pot is provided with a furnace *D*. Ore is introduced into the lowest pot as at F^1 and the pots are successively moved upward after a suitable period of treatment. The fused zinc chloride is introduced into the upper pot as at G^1, and the fused mixed chlorides after the reaction has taken place in the upper pot is poured into the second pot and subsequently into the lowest pot. In each pot there are three layers; molten lead *E* at the bottom which is designed

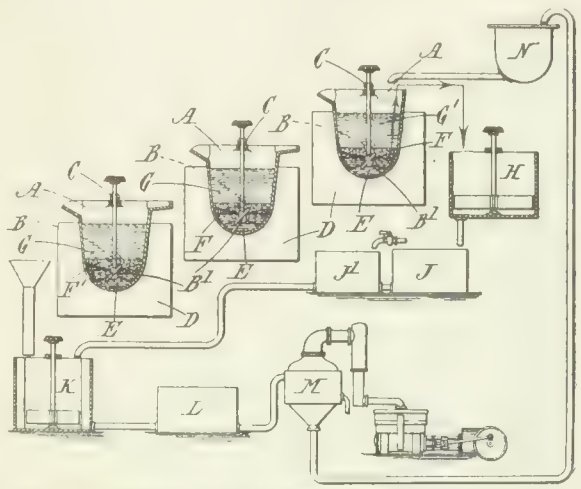

FIG. 1.—REMOVAL OF LEAD FROM ZINC CONCENTRATES.

to dissolve silver, the zinc ore of concentrate *F*, and the fused melt *G* consisting of zinc-sodium chlorides. The latter has a low specific gravity, and as the lead chloride dissolves in it the specific gravity is not greatly raised so that the melt floats on top. When the fused melt has been poured off the uppermost pot into the second, the lead bath (containing silver) is run off into a storage pot whence it can be drawn for further use or sent to a furnace for cupellation. The residue, consisting of heavy sulphide of zinc with some occluded chlorides of zinc and lead, is allowed to cool to about 250 deg. C., balled up by stirring and introduced into an agitation vessel *H* with hot water. The mass disintegrates, with solution of the soluble chlorides. The mixture is passed to the filter *J* from which the solution of chlorides is removed to the tank J^1 to crystallize out the lead chloride. The fused melt from the bottom pot may be poured directly into water in an agitating vessel *K*, from which the whole contents are discharged into a filter *L* where any residue is removed from the chloride solution.

The treatment of the melt for lead recovery permits of several alternative methods. The melt will usually contain suspended finely divided zinc sulphide formed by the reaction between the zinc chloride and galena, and this suspended zinc sulphide will not settle out of the melt with the same facility as will the zinc sulphide concentrate. One method of treating the melt, therefore, consists in introducing it into water, with or without the addition of a small quantity of HCl or H_2SO_4, so that the lead chloride and suspended zinc sulphide react to form lead sulphide or sulphate, and zinc chloride. Or, the lead chloride may be separated by crystallization and treated in the same manner with finely divided zinc sulphide. Again, the separated melt, containing zinc and other metallic chlorides, may be electrolyzed for the recovery of lead. Three alternative methods are available: first, the simple electrolysis of $PbCl_2$ whereby lead and chlorine are produced, the latter being used to chloridize zinc sulphide according to a process of Swinburne and Ashcroft; second, $PbCl_2$ is electrolyzed at a low temperature in the presence of suspended zinc sulphide whereby lead and sulphur chloride are obtained, the latter being used to chloridize zinc sulphide; third, the fused melt or recovered lead chloride is mixed in molecular proportions with the purest zinc sulphide available and electrolyzed at a high temperature, whereby lead and sulphur are obtained. The zinc chloride is

regenerated in each case for further use in the process. Electrolysis when sulphides are present in the bath is extremely economical of energy and apparatus. Anodes may be of carbon, and cathodes of molten lead, and the current required need not exceed a pressure of two volts with a current density of 500-1000 amp per square foot of anode surface.

As an instance of the working of this invention the inventor cites the following: Taking an ore assaying 40.2 per cent Zn, 10.6 per cent Pb, 8.5 per cent Fe, 9 per cent insoluble, 22 per cent S, and 16.7 oz. Ag per ton, he obtained a solid residue of unchanged zinc sulphide weighing when washed and dried 78 per cent to 82 per cent, assaying 50.6 per cent Zn, 0 per cent to 1 per cent Pb, 8 per cent Fe, 8.5 per cent insoluble and 0.25 oz. Ag per ton. The lead bath contained nearly all the silver content of the original ore. In the second stage of the process metallic lead, quite pure, and chlorine gas were obtained. When electrolysis was not used, the melt being dissolved in water with suspended zinc sulphide present, there was obtained a precipitate of lead sulphide or sulphate with some fine gangue, assaying about half gangue and half lead salt. Thus all the zinc is accounted for in one product, and all the lead in either of two other products. (1,011,897, Dec. 19, 1911.)

In case (*b*) mentioned before (lead concentrate containing small quantity of zinc), the proportion of lead sulphide is so high that it may be electrolyzed direct to lead and sulphur or chloride of sulphur, by so treating the ore as to dissolve the lead sulphide in lead chloride in a fused state, forming what the inventor terms lead chlorosulphide which is then electrolyzed. Thus the ore may be charged into a bath of fused lead chloride, where, after agitating with molten lead to extract the silver as before, it is allowed to stand some time. Owing

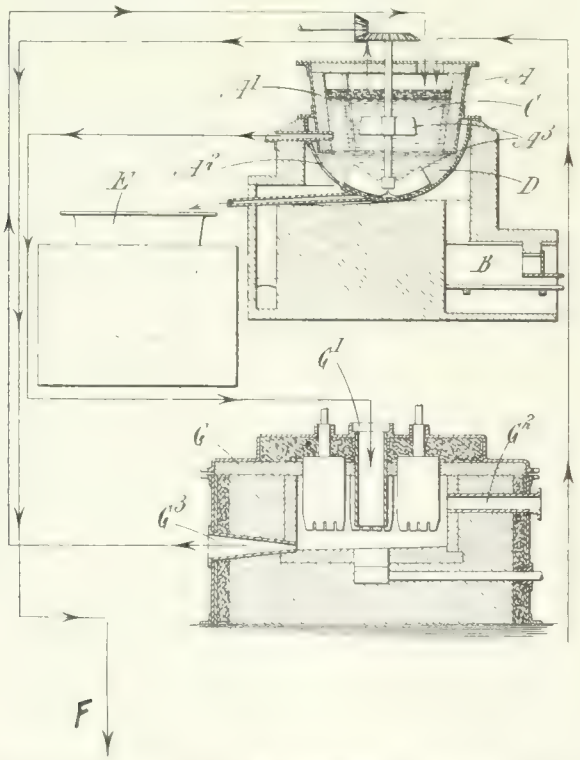

FIG. 2.—TREATMENT OF LEAD CONCENTRATE CONTAINING SMALL QUANTITY OF ZINC SULPHIDE.

to the high specific gravity of the melt, the gangue and zinc sulphide will float, leaving a clear melt of lead chlorosulphide below, which is tapped off and electrolyzed until all the sulphur is discharged and the corresponding lead recovered as pure metal. The lead chloride remaining from the electrolysis is then returned to the cyclic process. The floating matter containing the gangue and zinc sulphide is then suitable for treatment described above for product (*a*), shown in Fig. 1.

Fig. 2 shows the application of the process to lead concentrate containing a small quantity of zinc sulphide. *A* is a mixing pot with furnace *B*. The pot contains molten lead *D* for the recovery of silver, fused lead chloride bath *C* to dissolve lead sulphide, and a floating mass of gangue and zinc chloride. The lead may be tapped into a pot *E*, the lead chlorosulphide to an electrolytic vat at G^1, and the floating mass to the apparatus shown in Fig. 1, which would be placed

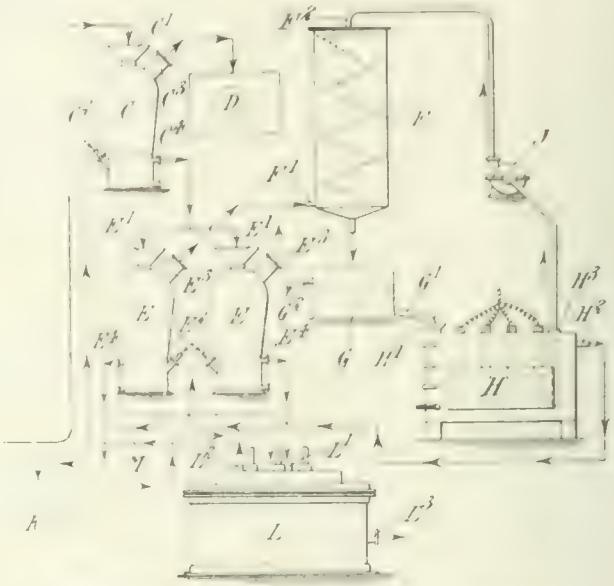

FIG. 1.—APPARATUS FOR CHLORINATION AND ELECTROLYSIS.

at *F* in Fig. 2. In the electrolytic vat the sulphur or chloride of sulphur passes out at G^2 for recovery and use, the reduced lead is removed through G^3, and the lead chloride remaining after electrolysis is complete is returned through the outlet G^2 to the mixing pot *A*. (1,011,898, Dec. 19, 1911.)

The final step in Mr. Ashcroft's invention consists in reducing the clean concentrated zinc residues obtained from the treatment of products (*a*) and (*b*), as described above. The inventor claims to have devised improvements on the method of dry chlorination invented by Swinburne and himself, the chief objection to which was the elimination of the gangue matter and the iron and manganese.

The present chlorine smelting process with electrolysis is carried out substantially as follows: The zinc concentrate is made into a cream with fused chloride of zinc. The cream is treated in a suitable vessel with chlorine or sulphur chloride which is forced in at the bottom of the vessel. At a temperature of 600° C. and upward, which is within the fusing and vaporizing points of zinc chloride, the reaction is most vigorous. The chlorine is rapidly absorbed and sulphur given off, the latter being condensed and saved. As the reaction is exothermic the temperature may be controlled by the rate of admission of the chlorine gas. The treatment is continued until all the sulphides are converted into chlorides, and additional supplies of sulphides may be added to the converter until a suitable quantity of chloride has accumulated. Toward the end of the reaction a little chlorine gas may escape, but this point is readily indicated by the emission of copious fumes of ferric and manganic chlorides. At the end of the reaction, the bath contains fused chlorides of zinc, iron and manganese, the latter two being in the "ous" condition.

The melt is now tapped into secondary converters, and more chlorine gas passed in. The result is that volatile ferric and manganic chlorides are driven off and absorbed in apparatus filled with 10 per cent to 15 per cent NaOH formed in a secondary electrolytic apparatus. The iron and manganese are thus recovered as hydroxides, and the caustic soda converted into sodium chloride, which is returned to the electrolytic ap-

paratus. The resulting "iron free" fused chloride of zinc is then treated by electrolysis for the reduction of zinc and recovery of chlorine.

Fig. 3 represents apparatus for carrying the chloridizing and electrolysis into effect. *C* is the main converter in which the fused sulphide and chloride of zinc is treated with chlorine, which is generated from the primary electrolytic vat *L*. The sulphur given off in this reaction is condensed in *D*. *EE* are secondary converters in which ferric and manganic chlorides are driven off by the addition of chlorine derived from a secondary electrolytic cell *H*, from which, also, is derived the NaOH solution used to absorb the iron and manganese chlorides in the absorbing apparatus *F*. The "iron free" fused zinc chloride is then electrolyzed in the primary cell *L*, or, if lead and silver have not been removed by the process described before, they are removed in *K* before electrolysis. *G* represents a filtering mechanism for the separation of iron and manganese hydroxides from sodium chloride solution, the latter being returned to the secondary cell *H*. (1,011,899, Dec. 19, 1911.)

A further method for the electrolysis of sulphides is outlined by Mr. Ashcroft as being an improvement on Swinburne's method, in which the latter electrolyzed sulphides in a bath of fused chlorides with the production of metals and sulphur. The objection to Swinburne's procedure was that the reaction required very high temperatures (about 600-700° C.) and very violent agitation of the melt to prevent settling. Mr Ashcroft proposes to carry on the electrolysis at lower temperatures at which chlorides of sulphur will be given off instead of sulphur, according to the following reactions:

$$MS + 2\,MCl_3 = 3\,M + SCl_4 \quad \text{Temp. } 350^\circ \text{ C.}$$
$$MS + MCl_2 = 2\,M + SCl_2 \quad \text{Temp. } 450^\circ \text{ C.}$$
$$2\,MS + MCl_2 = 3\,M + S_2Cl_2 \quad \text{Temp. } 550^\circ \text{ C.}$$

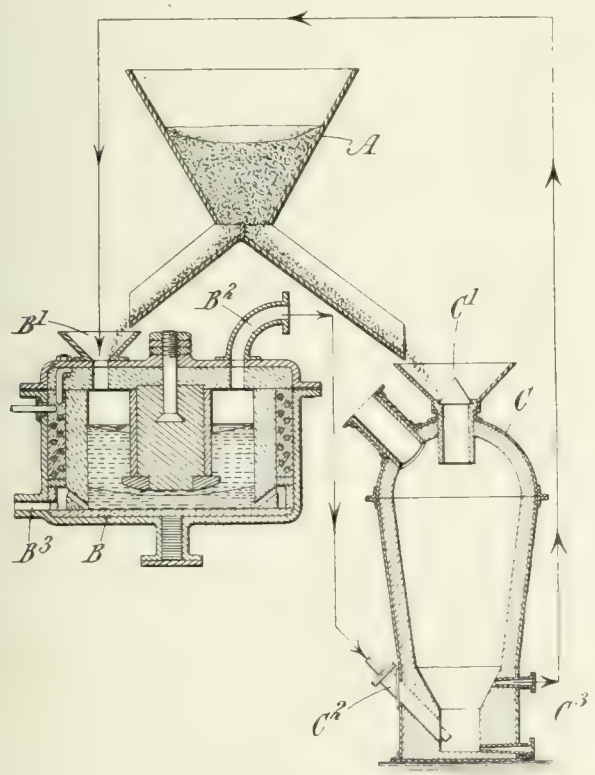

FIG. 4.—SULPHIDE ELECTROLYSIS.

The sulphur chlorides may be condensed and made to react with metal sulphides according to Swinburne and Ashcroft's method, forming sulphur and metal chlorides, the latter being added to the electrolysis bath to compensate for the chlorides decomposed by the above reactions.

When zinc is the metal to be recovered it is necessary first to remove iron, and this may be done by fractional electrolysis, using a cathode of molten lead to alloy the iron. A cathode of molten zinc may then be substituted and the zinc obtained therein. When lead is the metal under recovery it is not necessary first to remove iron as it is maintained in the ferrous state by the reducing action of the sulphides present and so does not interfere with the precipitation of the lead.

At the end of the reaction it may be desirable to separate zinc or lead from the chloride, and for this purpose sodium sulphide may be used, thus:

$$2\,ZnCl + Na_2S + 2\,Zn + SCl_4 = 2\,NaCl$$

Fig. 4 shows an arrangement for carrying this process into operation. Ore from the bin *A* is fed both to an electrolytic vat *B* and a converter *C*. In *B* the metal is reduced and the chloride of sulphur is conducted into the converter at C^2, where it reacts with ore forming metal chloride and sulphur. (1,011,900, Dec. 19, 1911.)

Synopsis of Metallurgical and Chemical Literature.

Gold and Silver.

Chispas Cyanide Plant, Arizpe, Mexico.—In the Columbia School of Mines *Quarterly*, for November, 1911, Mr. EDWARD L. DUFOURCQ gives details of the construction of a plant to cyanide an ore consisting of clean quartz carrying silver as argentite, polybasite and stephanite, with free gold at the rate of 1 oz. gold to 130 oz. silver per ton. An incomplete analysis of the ore follows: Insoluble, 80.6 per cent; Fe, 2.4; CaO, 1.6; S, 1.6; Sb, 0.3; Zn, trace; Pb and Cu, none. In addition to treating this ore, the plant was designed to handle an accumulation of the old tailings from stamp-amalgamation-concentration work.

Experiments on the accumulated tailings indicated that they would yield a recovery of 93 per cent of the silver and 98 per cent of the gold, with a cyanide consumption of not to exceed 3 lb. per ton, lead acetate 0.2 lb. per ton, and lime 2 lb. per ton. Thirty-six hours' agitation would be required if the tailing were ground to 150-mesh or finer.

The old mill consisted of Blake crusher, 20 stamps, three Wilfley tables and two amalgamating pans. In remodeling the plant for the use of cyanide it was decided to abandon amalgamation, increase the aperture of battery screens, concentrate on tables, and cyanide the table tailings after sliming them in tube mills.

A belt conveyor was installed to carry old tailings back to the mill where it is mixed with current tailing, the mixture being given the following treatment: It is first classified in a Dorr machine, the coarse product from which passes to an Abbe tube mill, 4½ x 20 ft., trunnion bearings, El Oro lining. The pebble charge consists of 16,000 lb. Danish pebbles. Cyanide solution is added with the sand to make a feed of proper consistency. The tube mill discharges into a second Dorr classifier from which the unground sand is returned to the tube. The slime passes to a Dorr thickener, 8 x 24 ft., and thence to any one of six air-agitation tanks, 12 x 36 ft.

The agitators are constructed as follows: Four rings of steel plates form the conical section of the tank, which is 27 ft. high. The top and bottom series of plates are riveted to angle irons at top and bottom of the cylinder. The cone bottom, which has a slope of 60 deg., also is riveted to the lower angle iron. The cone ends in a 10-in. cast-iron T, on one side of which is a blind flange and on the other a 10-in. gate valve. The agitation is accomplished by the Towne method. A central 10-in. pipe is placed in the agitator, reaching nearly to the bottom of the cone, and extending 2 ft. above the top of the tank. It is perforated with rows of four holes, 1 in. in diameter, the rows being 1 ft. apart except at the upper end of the pipe where, for 2 ft., they are 6 in. apart. Almost at the top level of the tank there are four 2-in. pipes extending outward and spirally curved from the central pipe to the circumference of the tank. Air is admitted through the blind

flange at the cone through a 1½-in. pipe which extends upward into the central tube for a distance of 18 in., terminating in a ball check valve. The tanks are discharged through the 10-in. gate valve at the cone, all tanks being connected with an Aldrich 6 x 7-in. triplex slime pump.

After agitation the tanks are allowed to settle, and about 8 ft. of clear solution may be drawn off to the gold solution storage tanks. The thick pulp is then pumped to a masonry tank 80 ft. above the Burt filter, from which the latter is fed with slime. This arrangement was adopted as preferable to direct filling from the pump, and is expected to provide for quick filtration without the excessive pressure which was developed by the pump when it was run at the speed requisite for rapid filling. A second masonry tank at the same height above the filter contains weak solution for washing the filter cake. Still another tank placed 290 ft. above the filter contains water which develops the hydraulic pressure to operate the filter door.

The gold solution is precipitated with zinc dust, two types of feeders being installed for comparative test. These are the Colbath and the Creston-Colorado types. The Creston-Colorado filter press is used to recover the zinc-gold precipitate. The author expects to publish later a full account of the comparative merits of these zinc dust feeders, also to give working costs at the plant.

Cyanidation of Nicaraguan Gold Ore.—The crude methods and enormous loss involved in the treatment of gold ore in the Pis Pis district on the Atlantic coast of Nicaragua, together with remedies for the existing conditions, are outlined in a paper published in the December *Bulletin* of the A. I. M. E. The author, Mr. Henry B. Kaeding, states that the future metallurgy of these ores depends on chemical, mechanical and economical considerations.

The ores consist of quartz carrying galena, pyrite, marcasite and chalcopyrite, and occasionally hematite, magnetite and shpalerite. Gold is associated with these minerals. Owing to excessive rainfall the ores above the water level are oxidized and leached, and have become highly acid. It has been the custom to crush, grind and amalgamate these ores, cyaniding the sand tailing and allowing the slime to run into the creek. The recovery has averaged probably 57 per cent. Caustic soda has been used to counteract acidity, with the result that iron and aluminium hydroxides have been precipitated and made settling or filtration impossible. As a consequence the opinion has prevailed that these ores cannot be cyanided and filtered. The ores below the water level have been let severely alone.

The author has experimented on all the ores and has found that extraction depends on fine grinding, and that filtration can be accomplished only by a rigid exclusion of sodium hydroxide from the process. A pulp consisting of 1 part of slime and 6 parts of water or cyanide solution will settle in 15 hours so that clear solution can be decanted, leaving a pulp of consistency of 2:1 which can then be filtered by vacuum apparatus. Dead settling in tanks is necessary, as the slightest vibration destroys the settling. The sulphides may be profitably treated with an extraction 90 per cent in 24 hours by grinding so that 90 per cent of the ore passes 200-mesh screen. This was done with a cyanide consumption of 2.9 lb., and with the use of 4 lb. lime per ton of ore.

Under the conditions which exist in this district all machinery would have to be of sectional design to permit of transportation. The author believes, however, that with a plant once erected and with water-power available at practically no expense, ore could be treated at a total cost of from $1.20 to $1.50 per ton. Chemicals cost there as follows: Potassium cyanide, 24 cents; lime, 10 cents, and zinc 14.5 cents per pound. Labor cost is $1.25 per day.

Electrolytic Assay of Gold Solutions.—At the assay office of the Kleinfontein Group in South Africa the following method of assaying gold solutions by electrolysis has been in use for four years. Mr. C. Crichton describes it in the *Journal* of the Chemical, Metallurgical and Mining Society of South Africa, Sept., 1911. The operation is carried on in a beaker, and suitable stand is provided to hold a number of beakers. The cathode connection rod extends along the stand just in front of the beakers and slightly above their tops. At suitable intervals a flexible wire is soldered to the rod, forming a connection for the cathodes. Above the beakers extends the anode rod to which are clamped anodes of gas carbon.

The cathodes are made from ordinary lead foil, a piece 9 in. long serving for each assay. The piece is notched along one edge which is to be the bottom of the cathode, thus providing for circulation of the solution. At one end of the strip a piece about ¼ in. wide is all but severed from the strip, and turned up to form a connection with the cathode wire. The strip is then formed into a cylinder, with the notches at the bottom and the connection projecting upward.

Current is provided by three 2-volt accumulator cells giving a terminal pressure of just over 6 volts. The stronger the solution is in KCN the greater will be the amperage; for example, a solution having a strength of 0.3 per cent KCN passes 0.1 amp, and one having a strength of 0.02 per cent KCN will pass but 0.04 amp. The accumulators are charged through a direct-current lighting circuit.

Ten A. T. of solution is used for an assay, which is completed in four hours. The lead cathodes are removed, dried, and cupelled with a little silver. The button is parted and weighed, the entire operation occupying about five hours, with little attention on the part of the chemist. Precaution should be taken against having the carbon anode in contact with the solution when the current is off, as precipitation will occur on the anode. The method has given excellent results, and has occasionally been checked with the regular evaporation and precipitation methods.

Copper.

Smelting and Refining at The Great Cobar, Australia.—A complete description of the smelter and refinery of this company appeared in the *Australian Mining Standard* for Oct. 12, 19 and 26, 1911, written by Mr. Donald Clark. We abstract some of the features that are of interest.

Smelting.—There are four furnaces arranged in line of their longest axes. Dimensions, 56 in. x 240 in. at the tuyeres. The furnace hearth plate is supported on parallel rows of eight cast-iron columns, 6 in. in diameter and 3 ft. 6 in. high. The hearth plates are made of cast iron, 3 in. thick, cooled below by water circulating through 1-in. coil pipes. A layer of silica 2½ in. thick is tamped on the plates, which serve as a bedding for a 12-in. silica brick bottom. Steel water jackets are arranged in two tiers, each 10 ft. high and 4 ft. wide, with a water space of 5 in. Tuyere openings are 5 in. diameter and 1 ft. 9 in. above the silica brick bottom. The tuyeres are spaced at 11½ in. centers, 4 to a jacket, or 20 on a side. The ends of the furnace are vertical but the sides have a bosh of 7 in. in the length of the lower jackets. The charging floor is 21 ft. above the tuyere level.

The furnaces are charged at the sides, having two counterbalanced doors on each side. Slag and matte flow continuously from water-cooled cast-copper spouts in each end of the furnace. Settlers are oval in shape, 9 ft. 6 in. x 18 ft. on the two axes, having a volume of 270 cu. ft. One of these is placed at each spout of each furnace, except at the outside spouts of the end furnaces, where circular settlers are installed, 18 ft. in diameter. The settlement of matte is as complete as it is possible to make it, and slag is sent to the dump from the settlers.

The ores smelted analyze as follows:

	Cobar.	Bourke.	Chesney.
Insoluble	16.24%	80.0%	68.0%
Alumina	6.50	2.8	8.0
Iron	40.40	9.0	12.0
Copper	2.60	1.3	3.5
Sulphur	11-20	...	...

A typical charge for the first matte is as follows:

Cobar	8000 lb. to 6600 lb.
1 part Chesney, 2½ Bourke	1000 lb. to 2400 lb.
Coke	450 lb. to 800 lb.

The matte produced runs from 16 to 22 per cent copper, and the slags assay about 38 to 40 per cent silica and 50 to 53 per cent ferrous oxide.

In the concentration furnace in which matte is concentrated for converting a typical charge is:

Raw ore (Cobar)	1800 lb. to 2500 lb.
Matte	3200 lb.
Slag	1200 lb. to 2000 lb.
Coke	500 lb. to 600 lb.

Requisite amount of Bourke gold ore.

The matte from this furnace carries 30 to 38 per cent copper, and the slags assay about 40 per cent silica and 54 per cent ferrous oxide.

The matte is reduced in acid-lined converters, the lining being composed of silicious gold ore (Bourke and Chesney) and clay mechanically tamped. The converter slags contain 1 to 2 per cent copper and are resmelted in the concentrating furnace. Blister copper is poled and cast into plates 2 ft. 2 in. x 2 ft. 4 in., weighing 215 lb. each.

The electrolytic tanks at the refinery are made of Oregon pine and are 2 ft. 10 in. high, 3 ft. 2 in. wide and 5 ft. 1 in. long. They are lined with 6-lb. lead which is protected by a hardwood grating. The wood exposed to the acid solution is prepared by boiling in paraffin. The tanks are arranged in terraces of eight, with three terraces in a row. The first, ninth and seventeenth tanks are on the same level. One dynamo is provided for each row, and a separate supply of solution is fed to each terrace of tanks. From the last tank in each terrace the solution flows to a sump from which it is elevated to storage tanks by air lifts. The solutions are heated to 130 deg. Fahr., by means of steam passing through hard lead coils. At this temperature the copper is deposited in a smooth even manner, and the resistance of the bath is lessened. The circulating solution starts with a strength of 12 per cent $CuSO_4$ $5H_2O$, and 12 per cent free H_2SO_4. If it becomes too rich in copper it is electrolyzed with insoluble anodes. The cathodes are removed in about fourteen days, melted and cast into bars weighing about 32 lb. The purity of the cast copper is tested with a Wheatstone bridge. The anode sludge has the following composition:

Copper	46.8%
Gold	1.5 to 4
Silver	15.5
Bismuth	0.7
Sulphur	2.2
Selenium	0.65

It is first dried and treated with strong sulphuric acid to remove copper. The residue is smelted with silica and sodium carbonate, and the Dore bullion cast into 100-oz. anodes. These are then refined electrolytically by the Moebius process.

Fire at Carbon Factory.

A fire at the plant of the American Carbon & Battery Company, whose offices are located at 509 Olive Street, St. Louis, Mo., destroyed one of the main buildings. The loss, being estimated at between $75,000 to $100,000, was covered by insurance.

A great deal of machinery but only a small amount of the large stock of carbon brush material and general carbon products were destroyed, as most of the latter products were in a building adjoining the one that burned. Enough finished and semi-finished material is in stock to supply their trade until the plant is rebuilt. Temporary quarters have been arranged and all orders are being filled promptly.

The battery plant was not injured in any way, and work has gone ahead without any delay in this department.

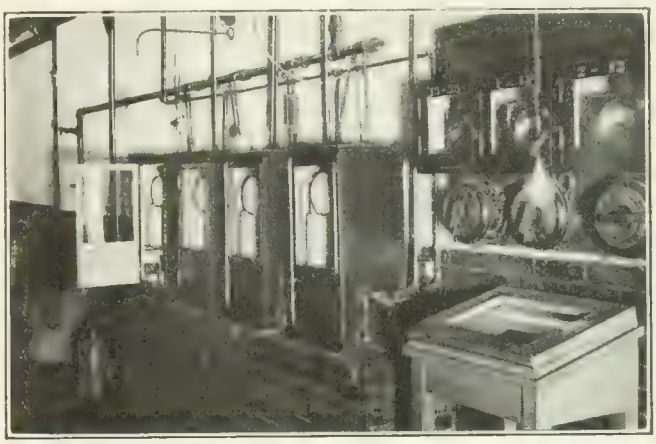
The carbon plant will be rebuilt at once, and will be of a very complete and up-to-date style. Special machinery will be put in to facilitate the manufacture of the new and improved line of motor and generator brushes which were put on the market a short time ago, and the company will continue to make the full line of standard and special carbon and graphite materials which it has heretofore produced.

Automatic Gas Analysis for Boiler House and Chemical Works Control.

In our Vol. IX, page 327 (June, 1911) a description was given of the Simmance-Abady automatic gas analyzers made by the Precision Instrument Company, of Detroit, Mich.

These are made in two types. In the first class, for non-corrosive gases, there is the precision Simmance-Abady CO_2 recorder which periodically analyzes samples of flue gas for the percentage of carbon dioxide which they contain and records this percentage on a chart. The adjoining illustration shows an installation of such CO_2 recorders, made by the Precision Instrument Company for the Solvay Process Company for a battery of twelve water-tube boilers of 279 hp rated capacity each.

In the second class are the recording analyzers for corrosive gases, such as SO_2, HCl, and chlorine gas, for use in chemical and metallurgical works, in paper mills, etc. They operate on the same general principle, but all the parts which



INSTALLATION OF CO_2 RECORDERS IN SOLVAY PROCESS COMPANY'S PLANT.

handle the gases are made, not of metal, but of glass, to withstand the corrosive action of the gas. Further, on account of the fumes from the gas, the indicating and recording mechanism is contained in an air-tight compartment.

Personal.

Mr. Gelasio Caetani, consulting metallurgist, has returned to San Francisco from a professional trip into British Columbia.

Mr. George E. Collins, consulting mining and metallurgical engineer, has been called to London on professional business. He is expected to return to Denver about Feb. 10.

Mr. Ivan E. Goodner, who is on the metallurgical staff of the Alaska-Treadwell Company, has returned to Alaska from a recent visit to San Francisco.

Mr. L. O. Howard, formerly a member of the faculty of Case School of Applied Science, Cleveland, Ohio, has gone to Green River, Utah, to take charge of operations of a company which is undertaking the development of vanadium deposits in that district.

Mr. Chas. Lindmueller is in charge of the new plant of the Goldschmidt Detinning Company at East Chicago, Ind., where they will manufacture pig tin. The plant is nearing completion and will be operating in a short time.

Mr. Henry P. Lowe, managing director of the Frontenac Mines, Ltd., Central City, Col., has just made a trip to Midvale, Utah, to inspect the operation of the Huff electrostatic separators, in successful operation there, and investigate their applicability to his ores.

Mr. L. H. Norton, consulting metallurgist of Silverton, Col., has gone to Mexico, where he will be engaged professionally until spring, when he will return to Silverton.

Mr. Richard A. Parker, of Denver, delivered the fourth in the series of "practical talks" inaugurated by the Colorado Scientific Society at Central City, Col., Jan. 13. His subject was "What a Mine and Mill Manager Ought to Know," and bore on the technical and commercial qualifications for good management.

Mr. E. P. Post, assistant in chemical department of the Carnegie Tech., Pittsburgh, has been appointed chief chemist of the Enameled Pipe & Engineering Company, Elyria, Ohio.

Mr. Georgie G. Vivian, until recently manager of the North American Smelter & Mines Company, at Golden, Col., has accepted a similar position at the Pittsmont smelter of the East Butte Mining Company, Butte, Mont.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (*Continued*).

No. 518,711, April 24, 1894, P. C. Choate, assignor to The Electrical Zinc Company.

Zinc. Precipitates a zinc fume from complex ores, as in his preceding patents. Then heats the fume with carbon in a vertical retort having a central perforated downwardly-opening pipe. The reduced zinc, with any lead, runs into the vessel below. If much lead is present, it is separated from the zinc by gravity. The zinc is run into slabs which are used as anodes in a solution of pure zinc sulfate, containing a little sodium chlorid to precipitate any silver. The cathodes may be plates of zinc. The bath is kept in motion by pumping the overflow back. In distilling the fume, contact with iron tools, or the use of coal containing iron, should be avoided.

518,732, April 24, 1894, Parker C. Choate, of New York, N. Y., Assignor to the Electrical Zinc Company, of New Jersey.

Zinc. Treats complex ores by roasting at a temperature insufficient to volatilize the zinc, driving off the excess of sulfur, mixing with coal screening, roasting on a grate to volatilize the zinc, some lead, antimony, arsenic, cadmium, etc., collecting the fume in bags, roasting the fume at a moderate temperature to re-volatilize the metalloids, and dissolving the residue in sulfuric acid and electrolyzing. Impurities in the solution may be initially deposited upon the cathode, or chemically precipitated, including lead sulfate. Uses anodes of lead or carbon and cathodes of zinc or copper. The freed sulfuric acid overflows from the cells and is carried to tanks, where it is neutralized by purified zinc fume.

526,099, Sept. 18, 1894, Paul Danckwardt, of New York, N. Y., Assignor of One-half to Charles Doehring, of Same Place.

Gold and silver. Treats finely pulverized ores with a solution of potassium cyanid and ammonium sulfate. Two forms of electrolytic apparatus are shown: one consists of two concentric horizontal cylinders, the outer a rotating cylinder of iron lined with lead having stirring blades and serving as anode, and the inner cylinder of amalgamated sheet copper serving as cathode. The gold and silver are deposited in the amalgam, the inner cylinder is removed and the amalgam scraped off. The second apparatus consists of a series of horizontal semi-cylindrical troughs having amalgamated inner surfaces arranged in echelon, serving as cathodes. Within each tank is a revoluble cylinder serving as anode.

528,[illegible] Oct. [illegible], 1894, Louis Pelatan, of Paris, France, and Fabrizio Clerici, of Milan, Italy.

Gold. Ores are crushed, the coarse gold removed by amalgamation, and the sludge fed into a series of electric amalgamators, consisting of wooden vats, in the bottom of each of which is an amalgamated copper disc, serving as cathode. A vertical shaft has stirring blades, and is surrounded by a zinc tube serving as anode. The electrolyte is a solution of potassium cyanid, not over 1/10 of 1 per cent., and of sodium chlorid or carbonate, 2 per cent. After treatment for two hours, the sludge is run off, the tailings filtered off and the gold precipitated by passing the solution through aluminum turnings.

BOOK REVIEWS.

Tables of Physical and Chemical Constants and Some Mathematical Functions. By **G. W. C. Kaye** and **T. H. Laby.** 6 [illegible] x 10 in., 133 pages. Price, $1.80 net. New York and London: Longmans, Green & Co.

A commendable collection of useful constants, not bulky or padded, not weighted down with obsolete and worthless data, but all through offering a most judicious selection of the very best. The thermochemical data given are, however, few and hardly satisfactory. Recipes for various operations, such as for silvering mirrors (p. 73), are out of place in such a work; the space should have been used in giving constants which have been omitted.

The type is well chosen to facilitate consultation, definitions are exact and up-to-date, and the work will be found in many cases an excellent substitute for the larger and more expensive collections of tables.

* * *

Electro-Analysis. By **Edgar F. Smith.** Fifth edition, 5 x 7½ in., 332 pages, 40 illustrations. Flexible leather binding. Price, $2.50. Philadelphia: P. Blakiston's Sons & Company.

Dr. Smith's book is so admittedly the standard book in English on electrochemical analysis that description or commendation is equally unnecessary.

This revised and enlarged edition contains, as new material, the essentials of all that has appeared upon electro-analysis during the past four years. Special stress is placed upon the utility of the mercury cup and the double-cup, by means of which some acids are estimated with greatest accuracy, and determinations and separations of the alkali metals are made with ease and comfort. These are very interesting examples of analytical laboratory methods borrowed in principle from industrial electrochemical processes.

Prof. Smith's book is better and more useful and illuminating than ever.

* *

A Manual of American Mining Laws. By **A. H. Ricketts,** of the San Francisco Bar. Size, 4½ x 6½ in. (11½ x 16½ cm), 500 pages. Price, $4. San Francisco: Scientific Publishing Company.

Mining Law, for the Prospector, Miner and Engineer. By **H. W. MacFarren.** Size 5 x 7½ in. (13 x 19 cm.) 356 pages, 33 illustrations. Price, $2. San Francisco: Mining & Scientific Press.

These two works are both excellent and commendable. They do not cover exactly the same ground or treat the subject in the same way. The first is a lawyer's compendium, the information being in strictly legal language, with copious references to legal literature; it is a work of great detail, laboriously and painstakingly worked out. It will be of great service to lawyers and to others capable of understanding legal terms and forms.

The second is a reference book, with the information put in a form to be easily grasped by the layman. The author is in the mining profession, and has been a mineral examiner of the General Land Office.

Both books are attractively printed and bound.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. X — New York, March, 1912. — No. 3

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

Rail Quality and Rail Duty.

No doubt it is fully realized by the representatives of the rail mills and the prominent railroad men who are now discussing the question of making steel rails better that the service which rails are expected to perform has increased greatly and that the problem is simply the engineering one of finding the rail which at the least expense will meet the requirements. The general public in the iron and steel trade perhaps does not fully realize how greatly the duty upon rails has increased, or how it chances that at this particular time the problem should require so much attention. The case, however, is a very simple one. From the time steam railroads were first built the duty has been constantly increasing through increases in speed, in pressure of wheel upon rail, and in density of traffic. Precisely in what measure each of these influences tends to wear rails out faster cannot be stated mathematically, but obviously they all do tend in the same direction.

In 1850 a 50,000-pound locomotive was considered heavy. Such locomotives generally had eight wheels, so that the heaviest weights per wheel generally ranged from 5000 to 6000 lb. Last year about a score of locomotives were ordered weighing more than 400,000 lb., involving an average weight per wheel of about 30,000 lb. Many were ordered between 300,000 and 400,000 lb., entailing an average weight per wheel of about 25,000 lb., while weights per wheel of locomotives ordered between 200,000 and 300,000 lb. weight averaged above 20,000 lb. per wheel. To a considerable extent it may be taken that in the matter of wheel pressures it is not the average, but the greatest wheel pressure which determines whether or not the rail is equal to the load, and it may be taken that wheel pressures have been multiplied by five in the past sixty years.

As to speeds we have no precise data, but it will probably be generally admitted that the speed of railroad trains has doubled in less than half a century.

Poor's railroad statistics give for many years the total track mileage in the country and the total ton-mileage of the country. From these we compile the average ton-mileage per mile of track: 330,000 in 1885, 380,000 in 1890, 377,000 in 1895, 550,000 in 1900, 630,000 in 1905, and 750,000 in 1910. It will be observed that in the fifteen years from 1895 to 1910 the average density of traffic has precisely doubled. This is the average, and upon the most traveled track there is reason to believe the density has more than doubled.

A multiplying of weight on drivers by five in sixty years represents an annual increment of 2.7 per cent; a doubling of speed in forty years represents an annual increment of 1.7 per cent, and a doubling in density of traffic in fifteen years represents an annual increment of 4.7 per cent. We have no reason to assume that these factors are of equal moment in destroying rails, but there is no harm in observing that the continued product of the three factors represents an annual

increment of 25 per cent which is now dealing in less than eight years.

It would be far from surprising, then, to find rail wearing out twice as fast as they did five years ago, while it would be surprising not to find them wearing out twice as fast as ten years, merely by reason of the increased duty expressed in the above figures.

It may be wondered why the problem of rail wear and rail breakage has come up with such prominence in the past few years, when the increase in service required has been so continuous, from the very beginning of railroading. The reply readily occurs. At first iron rails were used, and for many years they proved adequate to the service required, their weight being increased as necessary. There did come a time in the history of the iron rail, however, when it was regarded as very unsatisfactory, and many efforts were made to improve it, particularly by the manufacture of an iron rail with a steel head. Suddenly there came the Bessemer steel rail, which was by nature vastly superior to the iron rail. A sudden jump was made, and the improvement was amply sufficient to take care of the continued increment in service required for many years. The problem was laid on the shelf for a generation. In recent years it has become prominent. A few years ago railroad engineers started to increase the carbon rapidly in order to secure greater durability, and the increases were pushed to such an extent that breakages have now become rather frequent.

It is not, as in most engineering problems, a case of choice of evils. A certain percentage of breakage cannot be tolerated in order to provide greater wearing quality. The rails must be made safe first and durable afterwards.

A very distorted impression obtains in many quarters as to the average life of a steel rail. Much publicity has lately been given to statements that the rail mills formerly guaranteed five years' life to their rails, but will no longer do so. Such a guarantee is really an absurdity, for on some stretches of track the duty is many times as severe as upon other stretches. Over a limited mileage rails do wear out in a very few years, but on an average they last a very long time. For strictly replacement purposes the railroads have hardly yet reached an annual consumption of 1,000,000 tons a year, yet they have 360,000 miles of track. Laid in 90-lb. rails this would be 50,000,000 tons and in 80-lb. rails 45,000,000 tons. The average may be less than 40 lb., but the evidence is that the average life of a rail is nearer forty years than five years, which, as an average, is not so bad after all.

Unquestionably the improvement of the rail involves an increase in the cost. It is not, as carelessly assumed often, that the cost of all rails must be increased. When rails wear out very slowly the annual fund required against ultimate replacement is much smaller than the interest charge, but when rails wear out in a very few years the replacement expense is much greater than the interest expense. What is needed is a wide range of rail quality, at varying prices. All the rails should be made safe, which can be done by sacrificing a portion of the extreme of durability which has lately been sought by the unsafe method of increasing the carbon without heat treatment or other palliative. Then those which are subjected to heavy duty should be improved in wearing quality by methods which place themselves in position to know how much they can afford to pay, in price per yard of rail, for the varying degrees of heavy service.

It is probable that the chemical specification is of much less account than the physical structure—the rail must be made physically sound, free from slag enclosures, etc. The great success of titanium treatment points in this direction as the titanium acts chiefly as a purifier and only in special cases as an alloying element. The success of electric furnace treatment would also rest to a large extent on an analogous basis; since the resting of the steel in a non-oxidizing atmosphere in the electric furnace would permit thorough removal of all gases, slag particles, etc. In this respect the results obtained this winter on Northwestern lines with 5000 tons of electric steel rails (made from steel refined in the Heroult furnace) are significant, as there was not a single breakage of these rails, while there were some 200 breaks of Bessemer and open-hearth rails of the same weight and under the same kind of service on the lines in question. This seems to augur well for the ultimate success of the electric steel rail.

The Lead and Zinc Tariff.

Congress has stirred the metallurgical industry by a proposal to admit zinc ores to the United States free of duty, and to reduce the tariff on lead ores and products. The usual political hue and cry is accompanying the consideration of a subject which should receive unbiased treatment at the hands of disinterested parties, and it is more than likely that the true merits of both sides of the question will be totally obscured by the prominent part which politics will play. For this reason the feeling exists that, whatever action Congress finally may take, it will hardly be the result of a scientific investigation of the industrial condition, but rather of political trading to secure local benefits.

The Underwood bill, with its proposed tariff changes, has aroused almost unanimous opposition among ore producers and smelters alike. Under the leadership of the American Mining Congress the ore producers have been called upon to protect their mining interests from an influx of Mexican and Canadian ore, while the smelting interests have appeared on protesting committees in various parts of the country. In Salt Lake City a committee of mining men has endeavored to gather data and statistics on which they may base an intelligent opposition to the proposed reduction. In Denver, however, where the subcommittee of the Chamber of Commerce was composed of both smelting and mining men, the effort to adopt resolutions opposed to the reduction was vigorously antagonized and finally laid on the table. In Spokane, Washington, where mining men are directly interested in Canadian zinc and lead deposits across the international boundary, the sentiment favors the free entry of these ores.

The principal argument against the tariff reduction is that Canadian and Mexican ores would have an undue advantage over domestic production and consequently would glut the local market to the exclusion of the domestic product. On zinc ores containing 25 per cent or more zinc, the tariff is 1 cent per pound of zinc contained. On lead ores the tariff is 1½ cents per pound of lead in the ore. Again, it is claimed that the

cheap labor available in Mexico very favorably affects the cost of production in that country, and that Mexican zinc ore would have this additional advantage.

On the other hand, it is argued by a producer of zinc concentrates that, despite the fact that the past year has witnessed a wide margin between ore and spelter, a condition inuring greatly to the benefit of the smelter, there has been no corresponding benefit to the producer. In fact, the base price paid for concentrates has been reduced, and the producer has not been given as much benefit from market variations as formerly. Hence, although the spelter market has been in good condition, with a large European demand and steady home consumption, the producer has not reaped his share of the reward. The argument regarding cheap Mexican labor also is questioned. Writers on labor conditions in Mexico usually have agreed that the labor is cheap in every sense of the word, and that for responsible and reliable work skilled labor must be employed. In Canada the labor conditions are more nearly comparable to our own, but the ores are complex and require careful dressing to prepare them for market. The cost of transportation to domestic smelting centers also would be very great, and it is doubtful if much zinc ore could be shipped from Canada at a profit.

It is apparent from this brief view of the situation, that opinions differ slightly. But whatever the result of the political agitation may be, it is evident that there is some ground for feeling that more equitable conditions should exist between producer and smelter wherby the former will share the benefit accruing from any improvement in the industry

"Form-Value" and the Metallurgical Industry.

Economists say that value is created when any natural or artificial product is turned into some form useful to the community and that value is of three kinds: "time-value," "place-value," and "form-value." For instance, ice on the upper Hudson in winter has little value there. When brought to New York City it has "place-value" and in the summer it has an increment of value—"time-value." The 80 calories per gram of its latent heat of fusion abstracted from flavored milk turn it into ice cream and render it of "form-value." In each case there is a sort of commercial potential existing between consumer and the commodity and the owner of that commodity exacts his price for the use of the thermal potential of 80 calories.

Turning from this chilly subject to the mineral industry, one cannot fail to notice the marked increase of value given the mineral products of the United States by the various processes that give them "form-value." Take, for example, two tons of iron ore turned into one ton of steel. According to the degree of refining this steel sells at a price of from 1 cent to 10 cents per pound in the semi-finished form. When placed in an automobile it sells with the other materials for $1.00 per pound In the form of fine cutlery it sells for $5 to $10 per pound. In all of these forms it has acquired its "form-value" or commercial potential by the use of chemical and metallurgical processes that consummate the production of a refined metal. Without this special technical ability the mechanical industry could not exist. Indeed it is quite clear that the metallurgical and chemical industries stand in the same relation to the general manufacturing community as does the agricultural industry stand to the entire community. They each furnish the essential of the depending communities' existence.

In a most intense aspect, the electrochemical industry especially exhibits great power to impart "form-value" to natural products. This is natural for the use of such a powerful agent as the electric current should impress increased value on the raw material operated upon.

In the electrolysis of brine producing chlorine gas and caustic soda, 1 ton of salt worth on an average of $5 yields products worth six or seven times that amount. The graphitizing of impure coal makes a product a hundred-fold more valuable The same is true of the calcium carbide furnace, the carborundum furnace, and the ferro-alloys industries. In its extreme, almost ludicrous, instance we see the nitrification of air. Air has great utility but usually no value, for the supply is practically unlimited. Here the ratio of natural value to "form-value" has reached the limiting case, amounting to infinity.

Another example is the electrolytic refining of crude copper bullion carrying precious metals, where the "form-value" is great but assumes a cryptic aspect. The value to the community is enormous, for without its operation the electrical industry would be throttled for lack of high-conductivity wire. The price paid for this service is slight because it was not possible for the innovators to gain any monopolistic rights by patent protection. But nevertheless the enhanced "form-value" is present and society little appreciates what they owe to such pioneers as Edward Balbach and William Thum, Sr.

The total value of the mineral industry in the United States for the calendar year 1910 amounted to $2,003,744,869 according to the report of the United States Geological Survey. This is always given as "spot" value, *i. e.*, at that point of primary production. In general, there is but little "form-value" or "place-value" in this figure, stupendous as it is. If we consider the great increases in value probable by the working up of these crude products into more valuable forms, having in mind the fact that the ratio between value of finished product to crude product always is large and in one instance amounts to infinity, we arrive at a conclusion that the increment to our national wealth seen tangibly in our cities and factories is in greatest measure due to our production of mineral wealth. We have as a necessary corollary that our measure of national prosperity depends on the efficiency of the chemical and metallurgical and mechanical processes for the production of these essentials of modern civilization. All those who improve such processes and thereby heighten the prosperity deserve well of their fellows and of society. The technical schools and the universities, the engineering societies and the technical press, all combine to bring about increased general efficiency in the industrial world. It is a favorable sign that such endeavors are heartily received in times of apparent depression such as have been prevalent recently. With the great advance in the knowledge of physical chemistry, of all science, and of sound business principles in every manufacturing line and the wide diffusion of such intelligence, it is only fair to assume that the creation of "form-value" will be easier and more efficient in the future. It must be a pleasure and a privilege for each of us individuals to assist in such a great task.

Boston Meeting of the American Electrochemical Society.

The date of the annual meeting of the American Electrochemical Society has now been fixed. The meeting will be held on Thursday, Friday and Saturday, April 18 to 20, in Boston, Mass.

One of the features of the professional sessions will be a symposium on conductivity in its broadest aspects.

A fuller program will be published in our next issue.

Fixation of Atmospheric Nitrogen in Nitrolee, South Carolina.

In our Volume VIII, page 555 (October, 1910,) we referred to the decision of the Southern Power Company to enter, through a subsidiary company, the field of fixation of atmospheric nitrogen for the production of nitrate fertilizers for which there is a good market in the South.

The name of this subsidiary company is the Southern Electrochemical Co. and its plant at Nitrolee, S. C., has recently started operation. The plant has a capacity of 4000 h.p., the power being supplied from the two large waterpower plants of the Southern Power Co. at Great Forks and Rocky Creek.

The output is estimated as 8 tons of calcium nitrate per day of 24 hours. Calcium nitrate is in successful use in Europe as a fertilizer in competition with Chili saltpeter.

As has already been noticed, the Pauling process is being used in the South Carolina plant. It is already in successful commercial use in Tyrol and in France and has been described in some detail repeatedly in our former volumes, especially in our Volume VII, page 430, where the plant at Innsbruck, Tyrol, is described, and in our Volume IX, page 102 and page 196, where the plant at La Roche de Rame, near Briançon, Hautes-Alpes, France, is described.

The Patent Reform Problem and the Inventors' Guild.

In connection with the discussion of the patent reform problem in our January issue (page 8), we are glad to report the adoption of a resolution, addressed to President Taft, by the Inventors' Guild, which was particularly qualified to do so by the very high professional standing of its members. The resolution has been forwarded to Washington immediately after its adoption by the Inventors' Guild through its president, Mr. Ralph D. Mershon.

The strong point of the resolution is the request for the appointment of a joint Congressional committee, and it is expected that other technical and industrial organizations will join the Inventors' Guild in urging the appointment of this committee.

We herewith print this resolution in full.

"Whereas: The Constitution of the United States provides: 'The Congress shall have power to promote the progress of science and useful arts, by securing for limited times, to inventors, the exclusive right to their respective discoveries.'

"And whereas: This constitutional provision was intended to obtain for the benefit of the nation the publication of every new and useful invention in such full, clear, concise and exact terms as to enable any person skilled in the art or science to which it pertains to make, construct, compound or use the invention, after the limited time for which the exclusive right is secured to the inventor by patent; and thereby to secure for the nation the great benefit which, all experience shows, results to a nation from publishing inventions, in contradistinction to following a policy which would tend to encourage trade secrets, monopoly and trade combinations, which minimize the value of inventions to the nation;

"And whereas: A patent is in effect a contract between the government and the inventor by which the government, in consideration of the right to publish the invention for the benefit of the nation, agrees that in return for his satisfactory disclosures of his new and useful invention under reasonable conditions, to be determined by the government, it will secure the inventor for a limited time in the exclusive right to his new and useful invention.

"And whereas: An inventor, after having performed his part of the contract by having made proper disclosure of a new and useful invention to the United States government officials, is frequently subjected to unreasonable delay, expense and injustice before obtaining his patent, and after having obtained his patent is not equitably secured in his exclusive right as the Constitution intended that he should be secured in return for his disclosure in good faith of his new and useful invention; and as a consequence of this unfair treatment of inventor patentees, the United States is not obtaining, in the degree that it should, the national benefit of the best inventive work of its many able inventors.

"And whereas: The United States patent system has been evolved to its present condition without proper consideration of the rights of the nation, and of the inventors, who are the two real parties at interest, but on the contrary has been developed to its present condition almost entirely as the result of suggestions from persons who do not occupy the position of one of the parties to the contract which every patent represents; and who do not suffer damage from the delays, complications, injustice and expense characteristic of the United States patent system and the United States courts which hear patent causes; said damage being borne principally but indirectly by the nation and to a lesser degree, but directly, by the inventor-patentees.

"And whereas: It is a well-known fact that modern trade combinations tend strongly toward constancy of processes and products, and by their very nature are opposed to new processes and new products originated by independent inventors, and hence tend to restrain competition in the development and sale of patents and patent rights; and consequently tend to discourage independent inventive thought, to the great detriment of the nation, and with injustice to inventors whom the Constitution especially intended to encourage and protect in their rights.

"And whereas: Under existing methods of trying patent causes, an inventor-patentee of average means could not, at his own expense, carry to a conclusion an average patent litigation against a wealthy opponent, and therefore a few wealthy concerns usually acquire nearly all important patents in their field, to the great damage of the nation because of the restraint of competition and because of the resulting tendency of such inventors to seek protection for their inventions by trade secrets or else to cease inventive work.

"And whereas: Efficient protection by patent of new and useful inventions would offer to the average American manufacturer one of the best methods of meeting foreign competition and would, in addition, improve quality, reduce first cost and stimulate fair competition with resulting benefit to the entire nation.

"Resolved: The Inventors' Guild composed exclusively of independent and experienced inventor-patentees, does hereby respectfully ask the attention of the President of the United States to the urgent need of reforms in the patent office, and also in the courts which hear and decide patent causes; and hereby requests the President to recommend to Congress the advisability of appointing a committee to confer with experienced and representative inventors with the object of promptly accomplishing such reforms as will result in more effectively carrying out the intention of the Constitution; and to supplement such recommendations by such executive action as in his judgment seems likely to assist in accomplishing the needed reforms."

The Western Metallurgical Field.

Cyanidation at Cripple Creek.

The excellent work done last year at the Victor mill of the Portland Gold Mining Company, is attracting very favorable attention. Not since the successful operation of the Stratton's Independence mill has such progress been made in the treatment of low grade ore. Indeed the feature of the work at Stratton's was the utilization of old dump ore already mined, but at the Portland the chief merit lies in the fact that low grade mine ore extracted in the course of development work and in the mining of high grade ore is being made to pay a good profit. One feature of the metallurgy still remains undisclosed, viz., the details of the Portland cyanide process which embodies the chemical treatment to which the ore is subjected.

In January, 1911, the mill treated 8052 tons of ore, but the capacity of the plant was increased during the year so that in December, 1911, the total ore treated amounted to 12,285 tons. The gross value of the ore treated during the year was $3.51 per ton, but in December the value of the ore was only $2.80 per ton; but even on this lower grade ore the mill made a recovery of 80.5 per cent at a cost of only $1.1317. The extraction for year amounted to 81.4 per cent, netting a profit of $128,738.72 on rock which formerly was worthless to the company and thrown on the dump. As the total cost of construction of the mill, as officially announced, was only $338,580.96, it will be seen that the profits from another year's operations combined with those of the year and a half passed, will wipe out the cost of construction; and as there is a sufficient tonnage of low grade ore available to keep the mill running for a number of years to come, the profits will be a very important item to the company.

Among the improvements made at the mill since the beginning of this year, is the installation of a large Portland filter of the revolving drum type. The former equipment filters have the following dimensions: diameter, 12 ft.; face of drum, 9 ft.; capacity, about 45 tons of pulp in 24 hours. The new large filter is 14 ft. in diameter, with a 12-ft. face, and has a capacity of 90 tons of pulp in 24 hours. In addition to the larger capacity, there are advantages in the deeper submergence of the filter in the pulp, and better opportunity for washing the cake free of cyanide solution and dissolved metals.

At the Colorado Springs mill of the same company, the old equipment for chlorination is being abandoned, and the mill is being converted into a modern cyanide plant. The preparation of the ore, including roasting, will be retained as before. It will then be ground in tube mills in cyanide solution and filtered in two 200-ton Merrill presses similar to those in use at the Homestake mine and other modern plants where filter pressing is adapted to the ore. Zinc dust precipitation also will be installed, making the plant conform to the most approved ideas in cyanidation of roasted ores.

At the company's mines in Victor there has been installed a complete equipment for life saving and fire fighting. This step has been taken as a precaution against serious accidents arising from foul mine gases and fires. A corps of twenty men have been instructed in the use of the apparatus by the United States mines rescue service.

As a result of drainage through the Roosevelt tunnel, the Portland mine is now free from water, and preparations are being made to prosecute development work in the lowest level.

Stope filling with mill tailing is another innovation which has been adopted during the past year. This has a double advantage in that it enables the company to take care of its old stopes at less expense than before, and at the same time leaves the surface of the property available for mining work.

Chemical Engineering Education.

The Colorado School of Mines is at present offering a new course leading to the degree of Ch.E. (chemical engineer), in addition to its regular courses in metal mining, coal mining, metallurgy and mining geology, for which the regular degree of E.M. is granted. In the freshman and sophomore years, the work is the same in all courses, but in the last two years of the courses special instruction is given in the line which the student has elected. In chemical engineering the special work of the last two years will include: Junior year; analytical and organic chemistry, stoichiometry, industrial inorganic chemistry, metallurgy of iron and steel, fuels, electricity, steam engines and boilers, mechanics of engineering. Senior year: electrochemistry, theoretical chemistry, physical chemistry, industrial organic chemistry, technology of the non-metals, electrometallurgy, assaying, geology of the non-metals, ceramic geology, rare metals and English. In addition to this required work, there are offered many elective studies from which the student may select such as are appropriate to his work, and as many as are needed to complete his required number of credits.

Chemical engineering is as yet confined mostly to the eastern states, but with the growth and development of the West there will undoubtedly be found a field for men educated in the principles of chemistry and engineering. Realizing this future need, our Western schools are anticipating the student's requirements, and are gradually offering him courses along modern lines.

Mason Valley Copper Smelter.

Since this plant was blown in January 6, one furnace has been in steady operation and is now treating about 435 tons of ore daily. This tonnage is being increased gradually and is expected to reach 600 tons when that quantity of ore is available. It is expected that the annual output of copper will reach 20,000 lb. when both furnaces are in steady operation, and judging from the inquiries being received from outside companies it is probable that the treatment of custom ore will become quite a factor in the operation of this plant.

Phosphate Deposits.

The increase in the acreage of phosphate land withdrawn from entry by the government, leads one to believe that perhaps the United States contains within its borders the greatest phosphate deposits in the world. During January 214,749 acres in the state of Idaho, believed to be underlain with phosphate rock, were withdrawn on the recommendation of the U. S. Geological Survey. This makes a total of 1,167,137 acres withdrawn in Idaho. In Wyoming, 1,266,668 acres are now withdrawn; in Utah, 107,745 acres; in Montana, 33,950 acres; and in Florida, 35,640 acres. This makes a grand total of 2,611,140 acres withdrawn in the United States. There is now need of the enactment of a law which will permit development of this great resource, which is coming more and more into use as the country grows.

Cement Statistics for 1911.

Preliminary estimates of the production of Portland cement in the United States during 1911, have been given out by the Geological Survey. They are based on the returns made by 70 per cent of the manufacturers, and are believed to be correct within 2 per cent. The figures for 1911 are very close to those of 1910, and although at present an increase of 1.7 per cent is indicated, this may be decreased when complete returns are in. Certainly any increase in 1911 over 1910 will not approach the increase of 17.7 per cent which occurred in 1910 as compared with 1909. The average factory price per barrel, not including containers was 86.7 cents in 1911 as compared with 89.1 cents in 1910, a decrease of 2.68 per cent. It is observed that the factory cost increases greatly in the West as compared with the East. The cost in the Lehigh district was 76.3 cents per barrel; in the mountain states, $1.156, and in the Pacific slope, $1.407 per barrel. The Lehigh district produced about 1/3 of the total output; Kansas, Oklahoma and Central Texas stood second, and the Pacific slope plants third in the list of producers.

Copper Company Reports.

The tenth quarterly report of the Nevada Consolidated Copper Company, for the quarter ending December, 1911, shows that the average output was 5,236,084 lb. per month. The production for December, 1911, was only 4,679,674 lb. due to the severe winter conditions which prevented normal operations. The grade of the ore treated in this quarter was 1.04 per cent copper.

The fifteenth quarterly report of the Utah Copper Company, covering the fourth quarter of 1911, shows an average monthly of production 8,939,416 lb. The total production for the year 1911 was 98,436,224 lb. In the quarter under consideration the total tonnage of ore treated was 1,365,910 tons, of which the Magna plant handled 76 per cent and the Arthur plant 24 per cent. The average grade of the ore was 1.418 per cent copper. The grade is somewhat lower than usual owing to the fact that in steam shovel operations it has been impossible to eliminate all the capping, and some of this has been mixed with the ore. The average cost of copper per lb. during the quarter was 7.85 cents. This item also shows an increase which is ascribed to the lower grade of ore treated and increased cost of operation during the winter months.

The entire Magna plant was operated throughout the quarter, and the seventh remodeled section of the Arthur plant has been put in commission.

Goldfield Consolidated Mines Company.

The annual report of this company for the fiscal year ended October 31, 1911, contains interesting data regarding the remarkable mine and reduction plant at Goldfield, Nevada. During the year 330,549 tons of ore were mined, 330,062 of which were milled and the balance shipped. The net realization amounted to $7,526,846.04. The following tabulations give details of production and expenses.

PRODUCTION.

	Total Value	Per Ton
330,062 tons milled	$10,586,938.42	$32.08
487 tons shipped	173,262.18	355.77
330,549 total production	$10,760,198.60	$32.55
Loss in tubing	567,071.14	1.72
Values realized	$10,193,127.46	$30.74

EXPENSES

Mining and development	$1,109,457.95		$3.35
Transportation	30,628.70		.09
Milling	626,293.90		1.89
Concentrate treatment	124,315.70		.38
Marketing concentrate residue and by-products	244,583.94		.74
Marketing bullion	49,141.23		.15
Marketing ore shipped	17,103.92		.05
General expenses	181,334.80		.55
Bullion tax	126,319.26		.38
Income tax	27,001.19		.08
Total operating expenses	$2,536,180.59		$7.68
Miscellaneous earnings	37,730.30		.11
Net operating expenses		$2,498,450.29	$7.55
Realization from operations		$7,664,677.17	$23.19
Construction		137,831.13	.42
Net realization		$7,526,846.04	$22.77

The net realization from operations amounts to 69.95 per cent of the value of the total production. During the year the mill was in operation 96.37 per cent of the total time, and averaged 9.30 tons per stamp actual running time.

CORRESPONDENCE.

The Position of the Induction Furnace.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—I have read with interest a letter in your January issue from Mr. C. H. vom Baur concerning "The Position of the Induction Furnace," in which he takes exception to a statement which appeared in my recent article on "The Grönwall Steel Refining Furnace." This statement that "it would appear that the induction furnaces are on the decline," was intended to refer only to simple induction furnaces and not to those operating with a combination of induction and resistance heating, such as the Röchling-Rodenhauser furnace mentioned in Mr. vom Baur's letter.

The inability of the simple induction furnace to work with dephosphorizing and desulphurizing slags is admitted by the late Dr. Kjellin in his paper before the American Electrochemical Society, May 6, 1909, and further by Mr. Joh. Härden (who was closely associated with Dr. Kjellin in his work) in his recent paper on the Paragon electric furnace read before the Faraday Society, Oct. 2, 1911.

As the present demand is for furnaces which will melt cheap impure raw materials and refine them to produce high-quality steels, I think the future will show greater developments for arc furnaces than for those of the simple induction type.

Toronto, Ontario. J. H. Fa[illegible]

Discussion at San Francisco on Alaska Coal Mines

To the Editor Metallurgical and Chemical Engineering:

Sir:—On page 23 of the January number of Metallurgical and Chemical Engineering, as a part of a so-called "abstract" of the Discussion, at the San Francisco meeting of the American Institute of Mining Engineers, of the proposed operation of a coal mine in Alaska by the Federal Government, occurs, in a summary of my remarks, the following statement:

"One sentence of Dr. Raymond: "You cannot cure national evils," was so brutally pessimistic and so contrary to facts that his further tirade fell on deaf ears."

This quotation may possibly be an accurate *verbatim* report; for I cannot now recall the exact words which I may have used in *extempore* remarks which were to be subsequently replaced by more careful statements, published in the *Transactions* of the Institute. But I am perfectly sure—and my recollection in this particular is confirmed by others who were present, and whom I have consulted—that I did not use the words thus quoted, except as a part of a sentence, the whole of which conveyed a much less offensive meaning.

I was defending the familiar proposition that administration of the local affairs and interests of citizens should be intrusted, as far as possible, to local governments, because these are more accessible to complaints, and more sensitive to the demands of the public affected, than a distant central government could possibly be. In the course of this argument I said that maladministration in a given State could be remedied by such exposure and agitation as would make the people of that State hotly insist upon reform, but that we could not so easily cure such evils if they occurred in Federal administration, because it was so difficult (I may have said "practically impossible") to make the Congressional representatives of 48 States simultaneously indignant over the wrongs suffered by the citizens of one State only.

This is not pessimism, but simply common sense and notorious experience. I could have illustrated my proposition with recent instances of Federal usurpation and injustice, the victims of which were without redress. But I do not propose to offer either proofs or arguments in reply to the remark of your reporter.

My views on the subject of Mr. Bain's paper will be published by the Institute and it is not likely that I shall be tempted, before such publication, to notice again any misrepresentation of them.

New York City. R. W. Raymond.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—If Dr. Raymond, in publishing his discussion of Mr. Bain's paper, repeats the opinions and sentiments expressed in his *extempore* remarks in question, the reporter of the latter is perfectly content to leave the questions of the correctness of the report and of the justification for the criticisms to those who read the *Transactions* of the Institute.

South Bethlehem, Pa. Jos. W. Richards.

Refractories.

By Francis A. J. FitzGerald.

In the course of the past eight years the study of various forms of electric furnaces in the FitzGerald and Bennie Laboratories has involved considerable research work on the problem of obtaining suitable refractory materials. Attempts have frequently been made to interest some of those engaged in the manufacture of the ordinary well-known refractories in this problem, but the results have been very discouraging. This, however, is not surprising since in order to meet the special requirements of electric furnaces, and indeed many fuel-heated furnaces, it is necessary to go to the electric furnace for the refractory materials.

Last year the matter of making a study of refractories with the object of solving all sorts of problems of this nature and manufacturing the special materials necessary, was discussed very thoroughly with the Norton company. This company had already devoted a great deal of time to research work on "alundum" as a refractory material, and for some time had been engaged in the manufacture of silicon carbide which it sold as an abrasive under the name of "Crystolon." The pioneer work of Mr. Benjamin Talbot, as well as subsequent experiments by many others, had shown the value of silicon carbide as a refractory, so that the Norton company already had in its factories unusually excellent opportunities for the manufacture of two useful materials for this class of work. It thus seemed that a combination of the facilities of the FitzGerald and Bennie Laboratories and the various manufacturing plants of the Norton company would be a useful one for attacking the refractories problem. It was finally decided to carry on research work on the manufacture and use of certain refractory materials so as to be in a position to solve the problems which would be presented, and as a certain amount of progress has been made recently a brief account of the work done will be of interest.

Some of the refractory materials on which investigations have been carried on are as follows:

Alundum.
Crystolon (Silicon carbide).
  Crystalline.
  Amorphous.
Magnesia.
Lime

An account of some of the work done on the above materials follows:

Alundum.

It is not necessary to deal in much detail with this material as an excellent account of the work done by the Norton company was presented in a paper by Mr. L. E. Saunders at the nineteenth general meeting of the American Electrochemical Society[1]. It may be noted that alundum is made by purifying and fusing bauxite in an electric furnace. There are two forms, white and a brown material, the former being the purer. The white alundum has a melting point between 2050 deg. C. and 2100 deg. C., while that of the brown product is not more than 50 deg. lower. The linear coefficient of expansion of the white variety is 78×10^{-7} and of the brown 85×10^{-7}. The heat conductivity is much higher than fire brick. The specific gravity is 3.9 to 4.0.

Most of the work to which alundum has been applied so far is in laboratory apparatus, such as crucibles, muffles, combustion boats, cores for laboratory electric furnaces, combustion tubes, etc. Recently much experimental work has been done at the Norton Company's Research Laboratories on the production of pyrometer tubes, that is tubes for protecting the thermo-couples of pyrometers, and it is believed that an excellent tube can now be manufactured. The tubes made of alundum are more refractory than any of the porcelain or fire clay tubes, and, what is very important, have a distinctly higher heat conductivity. In using pyrometers in many kinds of work the changes of temperature are so slow that the heat conductivity of the pyrometer tube is not a serious consideration, but in other work it is of great importance to eliminate this lag in the temperature indications. How serious the heat lag may be will be shown below in discussing some of the work done with silicon carbide.

In Mr. Saunders's paper reference was made to experiments with alundum bricks. That these bricks are highly refractory there can be no doubt whatever. In the Norton company's experimental department a furnace roof was made of alundum brick and the remarkably high temperature these would stand without giving way demonstrated the point beyond doubt. The temperatures used in the experiments were so high that a roof built of silica brick was destroyed in five or six hours, while 40 or 50 heats at similar temperatures with the alundum roof failed to make it useless. On the other hand experiments with roofs built of alundum brick in a steel furnace did not give results which came up to expectations, although the temperatures were by no means so high as in the furnace referred to above.

The problem of constructing a good roof for a steel furnace of the surface arc type has been the subject of careful study at the FitzGerald and Bennie Laboratories in conjunction with the Research Department of the Norton company. Alundum brick made up in various ways have been tested in a small single-phase, two-arc steel furnace. These experiments have clearly shown that while alundum bricks will successfully resist the temperature of the electric steel furnace roof there are difficulties in the way of using them for that specific purpose. The bricks when used in the steel furnace roof showed a tendency to break off in layers and careful analyses soon showed that this was due to the action of the lime vapors rising from the intensely heated basic slag used in the furnace. The action in fact was altogether analogous to that pointed out by Hansen in his discussion of Saunders's paper, showing that in the steel furnace the stalactites which formed on the roof contained a relatively large percentage of lime and magnesia. The lime and magnesia vapors at high temperatures react with the alundum brick and thus shorten the life of the roof. The final conclusion reached, as a result of the study, was that while alundum brick could be made which would certainly outlast silica brick when used as a furnace roof, the increased life was not sufficiently great to warrant the extra cost of the special refractory in this particular case.

Crystolon.

This is the name given to the silicon carbide manufactured by the Norton company. It is obtained in two forms, crystalline and amorphous. The earliest work which has been published on silicon carbide as a refractory material was by Benjamin Talbot, who obtained a broad patent on the use of the material in that way.[2] Talbot says:

"I have found that carbid of silicon (which in the crystalline form is commonly called 'carborundum') if formed into bricks or compressed into a lining for metallurgical structure, is very refractory under high temperatures and resists the fluxing action either of basic or acid slags used in steel, iron or other metal manufacture . . . Either the crystalline or amorphous carbid may be used, preference being given to the amorphous carbid because that has hitherto been deemed a waste product and is consequently inexpensive."

Talbot in general proposes to use a binding agent such as tar, but does not limit himself "to any particular method of forming the lining," but claims, broadly, the use of carbid of silicon however applied as a refractory lining for metallurgical structures.

[1] Transactions of the American Electrochemical Society, Vol. XIX (1911), p. 333.
This journal, Vol. IX, p. 257; May, 1911.

[2] U. S. Patent No. 628,288.

In making repairs to the lining the carbid may be used dry or moistened with water or mixed with any appropriate binding agent, according to the nature of the repairs."

The amorphous carbide referred to by Talbot is, what may be called, the first stage in the formation of crystalline silicon carbide. When a mixture of sand and carbon is slowly heated to the point where a reaction occurs there is formed a greenish colored mass showing no crystalline structure, but consisting in large part of amorphous silicon carbide. As the process of conversion is gradual the product as taken from commercial furnaces is never chemically pure. At the outer parts of the charge, that is the parts furthest from the source of heat, there will be unconverted mixture mixed with the green-colored amorphous substance and near to the source of heat the amorphous substance will gradually grade into crystalline silicon carbide. Moreover, in the process of conversion it is possible that certain silico-carbides of the formula $Si_xC_xO_y$ are formed;[3] these corresponding to Acheson's "silioxicon." If, however, a fair sample of the amorphous material is obtained and purified by acid treatment, etc., an amorphous substance having the analysis corresponding to silicon carbide is obtained. A specimen prepared in this way gave the following analysis:

Silicon	69.41
Carbon	29.18
Iron and aluminium	0.59
	99.18

For a refractory it is, of course, unnecessary to have this specially purified material, the only necessary precaution being the avoidance of an excess of silica which might be present in unconverted mixture used in the furnace charge. Talbot calls attention to this point in his patent.

Since Talbot's original work on this material it has found a considerable market for use in various kinds of furnaces, etc., in the form of "carborundum fire sand." As a lining in various forms of resistance furnaces it gives most satisfactory results. For example, when it is desired to heat crucibles by embedding them in a resistor composed of granular carbon, trouble is often experienced at high temperatures by the melting of the fire brick forming the sides of the trough containing the resistor. If now the brick trough is made a little wider and then lined with amorphous silicon carbide to a thickness of 1 in. no trouble at all is experienced.

In many fuel-fired furnaces this refractory also gives excellent service in the form of bricks or linings, or even as a wash applied to the fire brick walls. It can be usefully applied in making repairs to furnaces and as a cement for setting up fire brick.

When this amorphous substance is heated to excessively high temperatures it becomes somewhat plastic and eventually in a reducing atmosphere is converted into the crystalline variety of silicon carbide. The fact that it becomes somewhat plastic at very high temperatures makes it possible, in special cases, to use it as a lining, etc., without any binding agent whatsoever, as indicated in the Talbot patent.

Amorphous silicon carbide is not a good heat insulator. Its heat conductivity while not very high is, nevertheless, distinctly greater than that of ordinary fire brick structures.

Formed at a higher temperature than the amorphous form, crystalline silicon carbide, or "crystolon," is a still better refractory material for many purposes. Under ordinary conditions it is infusible, but when heated to a sufficiently high temperature in a reducing or neutral atmosphere it is decomposed, silicon vaporizing and the carbon remaining behind as graphite. If heated to a sufficiently high temperature in a strongly oxidizing atmosphere, slow oxidation occurs, the carbon burning to carbon-monoxide and the silicon forming silica. The latter appears to form a protective coating which prevents further oxidation, or at least prevents it from proceeding rapidly.

Experiments have been carried out in the Norton company's Research Department on various articles made of crystolon grains or powders mixed with suitable binding agents, and so far the results obtained are found to be highly satisfactory; but more time and work have been expended on the study of crystolon made into various forms without the use of any binding agent. These articles are made according to a method patented by FitzGerald.[4] Silicon carbide in the form of grains or powder is mixed with some temporary binder, such as a solution of glue or dextrine, the mixture molded in the desired form and then heated in an electric furnace to the temperature at which silicon carbide is formed. This causes a crystallization or recrystallization of the silicon carbide and a strong very refractory article is obtained. These are known as "pure crystolon" bricks or tubes or whatever form these may be in order to distinguish them from bonded crystolon articles.

Most of the experiments which have been made with pure crystolon have been with bricks made of that material. As was already pointed out the bricks are infusible under ordinary conditions. The coefficient of expansion by heat is small, much less than that of silica for example. The heat conductivity is higher than that of alundum even. This is well shown in the figure where curves are given which illustrate the relative capacity for transmitting heat of silica, alundum and pure crystolon bricks. The method of obtaining the data from which the curves were plotted was to build a small furnace of the bricks under test and to place therein a resistor through which a measured current could be passed. Through a small hole in the wall of the furnace a thermo-couple was passed so that the temperature of the interior could be measured. The furnace was then heated with a definite current and when the temperature was constant both it and the watts were noted. This gave the amount of energy passing through the walls of the furnace for that particular internal temperature. In the curves the abscissae are temperatures in the furnace and the ordinates are watts, giving in that unit the rate at which heat is flowing through the walls. Curve 1 is for the pure crystolon brick, curve 2 the alundum brick and curve 3 a silica brick. It is very clear that the capacity of the crystolon brick for transmitting heat is very great compared to other

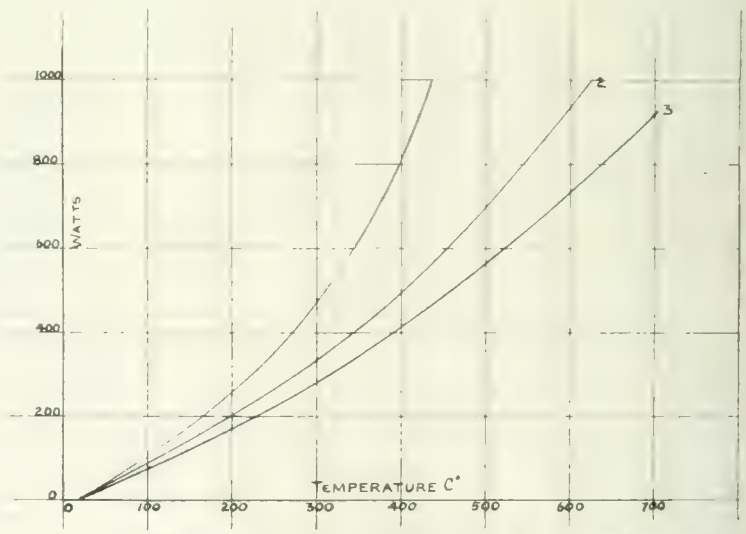

FIG. 1.—COMPARATIVE HEAT CONDUCTIVITIES OF (1) CRYSTOLON, (2) ALUNDUM, (3) SILICA

[3] *Electrochemical Industry*, Vol. II (1904), p. 439 *et seq*

[4] U. S. Patents Nos. 650,234 and 650,235

refractories. Thus when the temperature in the furnace is 435° the crystolon brick transmits 79 per cent more heat than the alundum brick and 117 per cent more than the quartz. The crystolon brick is, therefore, a very efficient refractory where it is desired to transmit heat through it; but on the other hand where good heat insulation is necessary it is important to back up the crystolon with a suitable heat insulator.

There have not been any thoroughly satisfactory quantitative experiments made on a large scale to study the efficiency of crystolon as a transmitter of heat, but two tests may be mentioned which give some indications on this point. A furnace having a capacity of 75 to 100 kw was constructed, in which the resistor heated the reaction chamber by radiation. Between the resistor and the reaction chamber was a septum built of crystolon tile 1 in. thick. Temperature determinations made with a thermo-couple on both sides of the septum showed a very small difference in temperature when the furnace was at high temperatures. In this relation, the form of curve 1 in the figure should be noted, as this indicates that the heat conductivity increases in marked degree with increased temperature.

The other experiment was a comparative one made with two pyrometer tubes, one made of a refractory clay and the other of graphite and crystolon. The dimensions of the tubes were identical, but the special tube was built up of two tubes the inner one being of graphite and the outer one of crystolon. The experiment was made by introducing the cold tubes into the furnace, the temperature of which was kept constant, and then noting the time taken for the pyrometer to come to a constant reading. In the case of the clay tube the time was 38 minutes, while the graphite-crystolon tube reached a constant temperature in 15 minutes. It was, moreover, observed that the clay tube gave a pyrometer reading 10 deg. lower than the other.

The most important study that has been made of the use of pure crystolon is in the building of the roofs of electric furnaces. The experiments have been made both in the Fitz-Gerald and Bennie Laboratories, where the crystolon brick were manufactured, and also in other works. The laboratory furnace was a small one having a capacity of about 500 to 600 lb. of steel, but it was possible to use a current as great as 150 kw. Moreover, in constructing the furnace the hearth was built very high so that in some cases the surface of the bath was only 8 in. distant from the roof of the furnace. This, of course, made the test a very severe one.

Certain characteristics of pure crystolon makes it necessary to construct the roof of the furnace in a special way. In the first place the high heat conductivity of pure crystolon would cause serious losses from a roof built in the ordinary way. This was clearly demonstrated by building a roof of pure crystolon brick, 9 x 4½ x 2½ in., with the brick placed so that their longest dimensions were vertical. When the furnace was worked on steel in this way it was impossible to heat it properly on account of the rapid flow of heat through the roof. After that the roof was built in two courses, the lower one consisting of crystolon brick laid so as to form a roof 4½ in. thick, and the second course consisting of fire brick also 4½ in. thick. This was found to be a perfectly satisfactory arrangement. It has also the advantage that the number of crystolon brick required to form a roof is reduced one-half in this manner.

The other characteristic of crystolon which makes a special construction necessary is its electrical conductivity at high temperatures. This phenomenon can be well illustrated by a simple experiment. If a rod of pure crystolon is wound with copper wire at both ends so as to make a good contact and connected to a source of electrical current, very little will pass, but if the rod is heated with a blast lamp to a high temperature the current will pass freely. Crystolon refractory articles made up with a small amount of a clay bond do not become conductors even at high temperatures, although the resistivity is considerably diminished. The following determinations of the resistivity of bonded crystolon have been made:

Temperature C°.	Resistivity (cm. cube)
20	318 x 10⁵
650	63 x 10⁵
800	32 x 10⁵
940	10 x 10⁵
1040	4 x 10⁵

It will be observed that although there is a considerable decrease in resistivity with rise in temperature, yet for most practical purposes the crystolon remains an insulator.

If now the pure crystolon brick were used to build an electric furnace roof through which two electrodes at different potentials passed there would be serious current leakage when the roof becomes hot if the electrodes touched it. It is, therefore, necessary to have a clearance between the electrodes and the brick by making the openings in the crystolon roof somewhat larger than is customary with the ordinary roof. On the other hand the heat insulating brick used on top of the crystolon roof form openings that are of the normal size. This method of constructing the roof is found to be perfectly satisfactory.

In the tests made at the FitzGerald and Bennie Laboratories it was found that when using ordinary brick and overloading the furnace there was no difficulty in completely destroying the roof in a single heat, but this was impossible in the case of the crystolon roof. When the crystolon roof is used it is possible so to overload the furnace that the magnesite lining is destroyed and yet the roof remains intact.

Experiments have also been made on 2-electrode steel furnaces in which the capacity was 2.5 tons of steel, and these in every respect confirm the results already mentioned.

It is certain that, provided a sufficiently high temperature is reached, there is a reaction between lime and silicon carbide, but so far as the tests made with the crystolon roofs go there is no appreciable reaction between the lime vapors from the slag and the brick.

The pure crystolon brick has been tested also in other ways. Thus, in one furnace in which a certain material was heated to excessively high temperature, it was found that a good grade of fire brick used outside the crystolon brick for heat insulating purposes could be melted down completely by the heat transmitted by the crystolon brick without in any way damaging the latter.

Other examples could be given, but enough has been said to show that this refractory material promises to have important uses, making it possible to do things which were impossible hitherto. For example, in the electric steel furnace not only may the space between the roof and the bath be made much smaller but the temperature may be forced to a higher degree without any risk of damage.

The crystolon brick is, of course, a somewhat expensive refractory and consequently much of the investigating work done on it has been in the direction of improving methods of manufacture so as to reduce the cost. So far as molding goes the problem is comparatively simple, but the development of a satisfactory furnace for "baking" the brick proved more difficult. However, a satisfactory furnace has been designed and worked until it appears to give excellent results.

Electrically Calcined Magnesia.

For many purposes, as is well known, magnesia is a most excellent refractory, but it has also serious faults. The most serious of these is an objectionable way of cracking when heated to a high temperature. This is, no doubt, in large part due to the remarkable way in which magnesia articles shrink when heated to high temperatures, corresponding to the increase in the absolute density. Moissan has described an experiment on this subject which is worth quoting here:

"The first specimen (of magnesia) had been heated for 6 hours in a furnace heated with an air blast and retort carbon as fuel. The second specimen consisted of magnesia plates, partly crystalline, which had been submitted for two hours to the action of the electric arc. The third consisted of a mass of magnesia weighing 50 grams and fused into a single piece in the electric crucible furnace.

"We obtained the following:

	Density at 20°
"1. MgO (furnace with blower)	3.577
"2. MgO (furnace plates)	3.587
"3. MgO (fused mass)	3.654"[5]

Moreover, Ditte has shown that magnesia gives the following densities:

	Density at 0°
At 350°	3.1932
Dull red	3.2482
White heat	3.5600[6]

Under the circumstances it is not surprising that articles such as brick and crucibles are apt to crack when heated to high temperatures.

It is obvious that the tendency to cracking exhibited by the ordinary calcined magnesite is less likely to be found in a material which has been calcined at the very much higher temperatures attainable by electrical means. An experiment which brought this out very clearly was as follows: A crucible was made of highly calcined magnesia made from Grecian magnesite. The crucible was embedded in a granular carbon resistor and the current regulated so as to heat up the crucible very gradually. The crucible was finally raised to an intense white heat, probably about 1500° C., and was then allowed to cool down gradually in the furnace. It was so badly cracked that it was absolutely useless. Another crucible was made in exactly the same way except that electrically calcined magnesia was used. This crucible was heated fairly rapidly to a temperature at which Seger cone N° 35 (supposed to bend at 1830° C.) was completely fused. The crucible was then allowed to cool down and was examined. A few very small cracks had occurred where a hot spot unfortunately developed during the process of heating, but otherwise the crucible was in perfect condition. The heat had been so intense that the outside of the crucible was slightly fused.

Several tons of magnesia have been electrically calcined and tested in a great variety of furnaces, and in every case excellent results have been obtained.

There is one other important point to note in regard to this highly calcined material. The ordinary calcined magnesia absorbs carbon dioxide gas forming magnesium carbonate more or less rapidly, but this does not occur at all, or with extraordinary slowness, in the case of the electrically calcined product. An experiment demonstrated this very clearly. Two porcelain boats were filled with electrically calcined magnesia and a highly calcined magnesia of the ordinary kind, respectively. In both cases the samples were finely ground so that the particles were of approximately the same size. The boats were placed in a tube through which a rapid stream of moist carbon dioxide gas was passed for 44 hours. At the end of that time the samples were weighed with the following results:

Sample.	Per cent increase in weight.
Ordinary calcined	31.30
Electrically calcined	0.00

In the preparation of this magnesia it is possible to use an arc furnace, but the method is not altogether satisfactory on account of its cost. It is unnecessary, and in fact disadvantageous in many ways, to fuse the magnesia. Accordingly a resistance furnace has been worked out which will calcine the magnesia to the desired degree.

[illegible]

Fused Lime.

Some hundreds of pounds of lime have been fused in the electric furnace and an interesting product obtained. Little work has been done on the use of this material as a refractory, but certain of its properties indicate that it is worth while studying it. It appears that in this form it is a much better conducor of heat than ordinary quick lime. Blocks cut from the fused product stand heating followed by sudden cooling very well. One such block was heated to redness with a blast lamp and while still under heat cold water was poured on the block without producing any change. Fused lime resists exposure to moist air remarkably well, for while it will eventually slack this is a process of days instead of hours. Even when boiled with water, hydration proceeds very slowly.

Conclusion.

Other refractory materials are under investigation and some will undoubtedly give interesting results. The study of the subject indicates very clearly that every refractory problem requires individual study for its solution, and that for at least some of these problems suitable refractory materials have already been discovered.

FitzGerald and Bennie Laboratories,
Niagara Falls, New York.

Concentration by Flotation of Dry Ore Pulp.

By H. C. Parmelee.

The systems of concentration by flotation that have been exploited in the past decade exhibit a variety of applications of one or two underlying principles. The use of oil and acid mixtures, with or without the application of a vacuum, is common to most of them; and with the exception of the method to be described herewith, all of them treat pulps which have been submerged in water. In some of them the floating concentrate is formed as a thin film, approximately one particle deep, while in others it gathers as a thick scum on the surface of the liquid in the treatment tank.

The method of flotation here described is the invention of Henry E. Wood, of Denver, Colo. It falls within the class of film flotation processes, but is distinguished from these and all others by the fact that neither oil nor acid is used, and that the ore pulp is floated in the dry state just as it comes from the crushing machine. The basis of the separation lies in the difference in the effect of gangue and mineral particles on the surface tension of water.

Before proceeding to a dscription of the machine and its operation some consideration of its principles may not be amiss. The working of the process involves the physical properties of cohesion and adhesion and their attendant phenomena of surface tension and capillarity. It is well known that a liquid behaves as though its surficial film is in a state of tension tending to contract. This is usually ascribed to the molecular attraction of the liquid particles. Under normal conditions water exhibits this phenomenon of surface tension in a very high degree, more highly, perhaps, than any other liquid except mercury. The state of tension on the surface, however, is modified or affected by the presence of a solid particle in contact with the surface of the liquid. The surface of water, for example, near the sides of its containing vessel, or surrounding any object placed on its surface, is not truly horizontal. If the solid is wetted by the water, the surface of the liquid is slightly concave in that vicinity; if the water does not wet the solid, the liquid surface is slightly convex along the line of contact. The concavity and convexity are capillary phenomena and depend respectively on the relative molecular attraction of the liquid particles for each other (cohesion), and the attraction of the liquid particles for the solid (adhesion).

In case the adhesion between the solid and liquid is greater than the cohesion of the liquid particles, we find capillary elevation of the liquid surface and a wetting of the solid. If the cohesive force is the stronger, we find depression of the liquid surface and the solid is not wetted. This action is confined to thin surficial films or layers of the solid and liquid. The law[1] is thus stated: The liquid will be elevated in a concave curve or depressed in a convex curve by the side of the solid according as the attraction of the liquid molecules for each other is less or greater than twice the attraction between liquid and solid.

The temperature of the liquid exerts an effect on the action of the adhesive and cohesive forces, increasing the capillary action of the liquid surface as the temperature rises. In general, when solids are specifically heavier than the liquid, those which become wetted will sink and those not wetted will float.

Minerals Which Float.

An investigation of the principles underlying flotation processes was published[2] in 1911 by Kenneth A. Mickle. Among other points he studied the behavior of minerals and metals toward cold and hot water. He found that when minerals are carefully deposited on the surface of water many of them float, while others sink immediately; also that considerable weights could be supported by a thin film of floating mineral. He gives the following list of minerals which floated on the surface of cold water: Galena, blende, sulphur, azurite, malachite, rhodonite, garnet, calcite, mica, telluride of gold, pyrite, pyrrhotite, wolfram, cassiterite and serpentine. The list is open to question from a commercial standpoint, however, for apparently the tests were made on a small surface of water, e.g., on a cylindrical graduate or beaker, where the surface tension did not have free and unobstructed play. If the tests

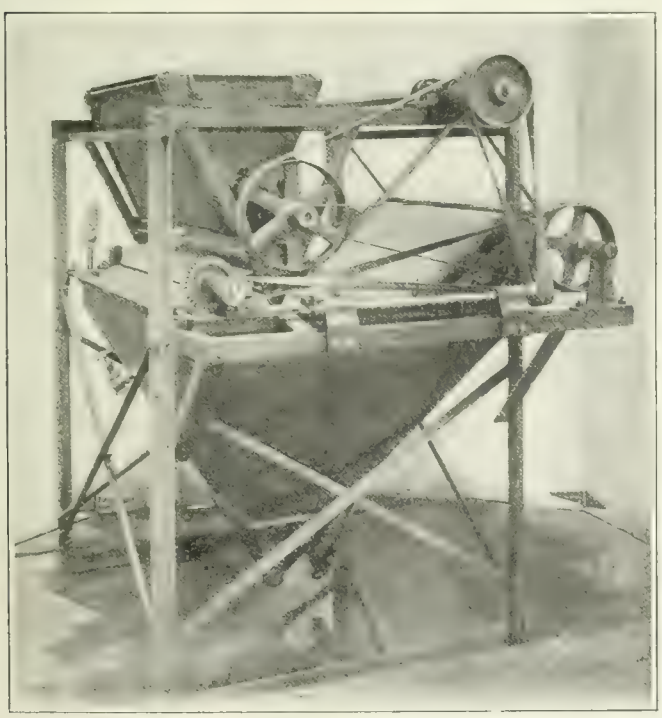

FIG. 1.—WOOD FLOTATION MACHINE.

had been made on a large surface of water, say 10 sq. ft., there is little doubt that some of the minerals mentioned would have sunk. This will be indicated later.

On hot water the behavior of the minerals was different, most of them becoming wetted and sinking after floating for a few seconds only. This apparently was due to the decreased surface tension of the water.

The Wood Machine.

The Wood machine for flotation of dry-crushed ore is illustrated in two views in Figs. 1 and 2. Fig. 1 shows especially the feed and Fig. 2 the discharge end. The machine consists of an angle-iron frame supporting a feed hopper, shaking feed plate, partly submerged feed roller, belt conveyor for removing concentrate and tank of water on the

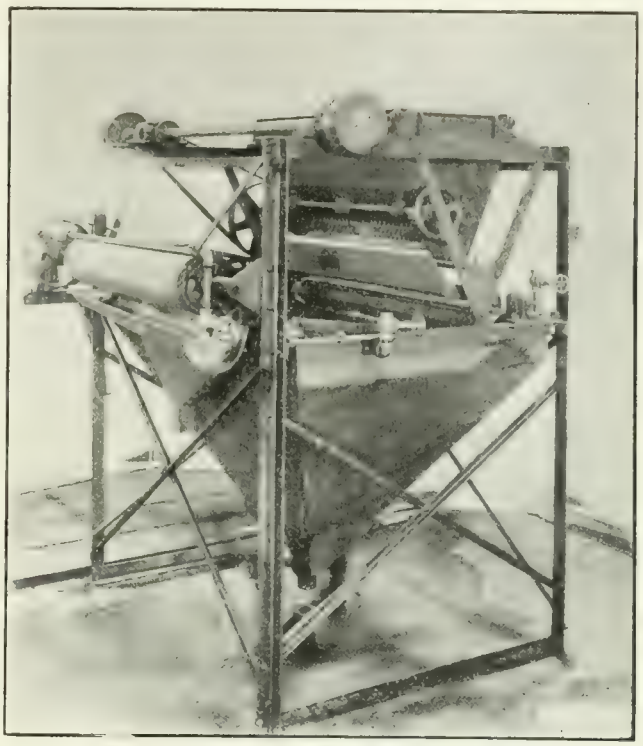

FIG. 2.—OTHER VIEW OF FLOTATION MACHINE.

surface of which flotation occurs. The floor space occupied is about 4 ft. by 6 ft. and the height 6 ft.

Referring to Fig. 1: The dry ore, suitably crushed, is fed from the hopper onto a shaking tray, which in turn delivers a thin stream of ore onto a partly submerged revolving roller, shown at the left of the tank. The roller is covered with some form of corrugated rubber, the size of the corrugations depending on the mesh of ore under treatment, being larger for coarse pulp. As the roller revolves (clockwise as seen in the figure) it elevates a certain quantity of water. The ore pulp falling onto the roller in a thin stream is thus immediately exposed to the wetting action of water, and is then delivered onto the surface of the water in the tank. The gangue particles become wetted by capillary action and sink, while the mineral concentrate tends to float and soon covers the entire surface of the water. In order to facilitate the movement of the film of concentrate across the tank to the belt conveyer gentle streams of water from submerged perforated pipes are directed in a suitable manner against the under side of the film.

On reaching the discharge side of the tank the concentrate is removed by a belt conveyer, the tail pulley of which is below the water surface in the tank. The point of discharge is better shown in Fig. 2, where the head pulley appears above and outside of the tank. Water from a perforated pipe washes the concentrate off the belt into a hopper. The flotation tailing sinks in the large tank, whence it can be removed, if desired, for subsequent treatment on concentrating tables or discharged as clean tailing.

In the course of Mr. Wood's experiments many interesting facts have been discovered regarding flotation of minerals on water. He finds that the sulphides generally exhibit a more or less marked tendency to float, as also do the tellu-

rides, graphite and metallic gold and silver. These substances are not easily wetted, and consequently cannot get beneath the surface of the water. The sulphides of copper, lead, silver and molybdenum, for example, strongly tend to float, while those of iron and zinc show this property in a less marked degree. Thus preliminary separation of some minerals can be made by the flotation process, as will be shown later. In the case of a mineral which shows a strong tendency to float, e.g., tetrahedrite it is possible by preliminary flotation to make a recovery of mineral which in the ordinary processes of concentration would be lost. In extremely favorable instances, as in the case of molybdenite and graphite, it is possible to produce concentrates that are not recoverable by ordinary methods of concentration.

Oxidized minerals and gangue substances generally tend to sink when brought onto the surface of water, becoming wetted by capillary elevation of the liquid surface and ultimately being completely immersed. In this respect the list of floating minerals given by Mr. Mickle is apparently at fault, for he includes azurite and malachite, neither of which is commercially amenable to direct flotation.

The mode of preparation also affects the results obtainable by this system of flotation. The degree of fineness to which an ore should be crushed in order to secure best results can be determined only by experiment; but in regard to the manner of preparation there seems to be little doubt that the ore should be *crushed* and not *ground*. The ball mill and rolls yield a more suitable product than do the tube mill and disc grinder. In the former machines we get a fracture due to a crushing blow, while in the latter we get reduction by abrasion. The crushers produce tabular particles whose surfaces are more cleanly fractured, while the grinders produce surfaces that are irregular and less well defined. The grinders also produce an excessive amount of fine mineral, thereby increasing possibility of loss. Inasmuch as this form of flotation is vitally concerned with the relations of surfaces, it is not difficult to see wherein one method of preparation might be superior to the other.

Another point which is indicated in some experiments, although not as yet fully determined, is that long exposure of crushed ore to the air is detrimental to flotation. In other words, the best results are obtained from freshly crushed ore. Perhaps incipient oxidation of the sulphide surface is sufficient to destroy its effect on surface tension; but whatever the cause may be, the results are as stated.

As with other forms of concentrating apparatus, the capacity of this machine varies with the ratio of concentration. If the ore contains much mineral which will float the capacity is naturally lower than in the opposite case. The surface of the water must not be crowded with concentrate, as otherwise the mineral particles may become wet and sink. Over a wide range of ores, however, the capacity has varied from 1000 to 2000 pounds per hour.

Results of Tests.

The results from a series of tests made specially for the writer are given below. The ore contained chalcopyrite and pyrite, silver being associated with the former. For all tests except No. 8 the ore was crushed in a Krupp ball mill. For No. 8 the ore was ground in a disc pulverizer. The effect of ball mill crushing in producing tabular mineral fragments was specially noticeable. In reconcentrating the flotation tailing on a Wilfley table thin tabular pieces of pyrite were observed to float like mica and pass into the tailing. The gangue associated with the copper and iron minerals in this ore was very heavy, apparently containing a manganese mineral. As a result it appeared to a large extent in the Wilfley concentrate, making a low grade silicious product. A screen analysis of the flotation concentrate [illegible] pulp showed that 24.7 per cent of the weight of that product was between 16 and 40-mesh in size, thus showing that not only fine but appreciably coarse mineral will float by this process. The fact that the [illegible] size must not be construed as indicating the coarsest pulp that can be floated. As a matter of fact, 10-mesh pulps can be treated successfully; but at 16-mesh we practically reach the coarse-grade limit of table concentration.

Test No. 1.—Ore ground to 30-mesh [illegible] and concentrated without sizing on a Wilfley table only:

	Weight grams	Assay Ag. oz.	Assay Cu. %	Distribution Ag. %	Distribution Cu. %
Ore taken, 30-mesh	2268	2.80	1.51	....	....
Wilfley conc. (9.11:1)	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Wilfley tail	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Net [illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

This shows the inefficiency of ordinary wet dressing on this ore. More than half of the silver and copper appear in the tailing.

Test No. 2.—Ore ground to 40-mesh and treated by flotation only:

	Weight grams	Assay Cu. %	Distribution Cu. %
Ore taken, 40-mesh	2268	1.50	....
Flotation conc. (22.14:1)	[illegible]	26.66	[illegible]

The ratio of concentration, grade of concentrate and percentage of recovery are higher than on a Wilfley table.

Test No. 3.—Ore ground to 30-mesh and concentrated by flotation. Reconcentration of flotation tailing on a Wilfley table without preliminary sizing:

	Weight grams	Assay Ag. oz.	Assay Cu. %	Distribution Ag. %	Distribution Cu. %
Ore taken, 30-mesh	2268	2.80	1.51	....	....
Flotation conc. [illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Wilfley conc. [illegible]	[illegible]	[illegible]	[illegible]	[illegible]	5.46
Total conc. (11.34:1)	200	18.45	11.95	56.95	70.28

This shows higher copper recovery at 30-mesh than in test No. 2 at 40-mesh. Additional small recovery is also made by the Wilfley table.

Test No. 4.—Noting the higher copper recovery by flotation at 30-mesh as compared with 40-mesh, this test was made on 20-mesh pulp to see whether additional improvement would result from coarser crushing. The flotation tailing was reconcentrated on a Wilfley as before:

	Weight grams	Assay cu. %	Distribution cu. %
Ore taken, 20-mesh	1000	5.13	....
Flotation conc. (16.96:1)	112	30.28	34.80
Wilfley conc. (7.27:1)	261	17.33	46.47
Tailings	1527	1.20	18.79
Total conc. (5.09:1)	373	21.22	81.27

This shows further improvement in the grade of flotation and table concentrates, as well as higher percentage of recovery.

Test No. 5.—This was made on pulp passing 16-mesh to ascertain the effect of still coarser crushing. The flotation tailing was reconcentrated as before without sizing:

	Weight grams	Assay cu. %	Distribution cu. %
Ore taken, 16-mesh	1500	6.01	....
Flotation conc. (13.88:1)	108	30.60	36.68
Wilfley conc. (5.43:1)	276	17.42	53.38
Tailings	1116	0.82	10.79
Total conc. (3.9:1)	384	21.13	90.06

Here we find about the same grade of concentrates as in the preceding test, but with about 9 per cent greater recovery.

Test No. 6.—This was made with 16-mesh pulp in a similar manner to test No. 5, except that the flotation tailing was sized for concentration on the Wilfley table:

	Weight grams	Assay Ag. oz.	Assay Cu. %	Distribution Ag. %	Distribution Cu. %
Ore taken, 16-mesh	2268	2.80	2.30	....	....
Flotation conc. (5.46:1)	415	23.70	26.35	55.65	66.10
Wilfley conc. [illegible]	503	8.40	8.65	[illegible]	27.24
Tailings	1247	....	0.62	....	4.69
Total conc. (2.47:1)	918	15.31	16.81	79.58	93.34

The total recovery is slightly increased over that of test No. 5.

[illegible] College Philosophy.
Engineering and Mining Standard, April 5, 1911, p. 7, 1911.

Test No. 7.—Similar in all conditions to test No. 6. The recovery of silver is appreciably higher. The flotation concentrate contained but 3.88 per cent silica.

	Weight grams	Assay Ag. oz.	Assay Cu. %	Distribution Ag. %	Distribution Cu. %
Ore taken, 16-mesh	4500	5.20	4.50	....	....
Flotation conc. (17.73:1)	678	27.90	24.25	74.16	74.54
Wilfley conc. (6.48:1)	699	7.60	4.28	22.52	14.67
Tailings	2965	...	0.35	....	5.08
Not accounted for	....	...	...	....	5.71
Total conc. (13.47:1)	3326	17.20	13.72	96.68	89.21

Test No. 8.—This test was made to show the effect of grinding as compared with crushing. The ore was ground to 16-mesh in a disc pulverizer and then concentrated by flotation. The results are to be compared with those of the other tests on 16-mesh pulp. The difference in recovery is not as great at 16-mesh as it probably would be with finer pulps:

	Weight grams	Assay cu. %	Distribution cu. %
Ore taken, 16-mesh	2268	6.25	....
Flotation conc. (5.54:1)	409	23.02	66.49

The recovery is lower than that by flotation in test No. 7 and about the same as that in test No. 6.

Test No. 9.—As a matter of interest in connection with these tests one was made using a film of oil on the surface of the water. The ore was floated dry in the usual manner, the oil merely acting as a transporting medium:

	Weight grams	Assay cu. %	Distribution cu. %
Ore taken, 16-mesh	1000	4.50	....
Flotation conc. (6.53:1)	153	23.05	78.45
Wilfley conc. (10.2:1)	98	4.40	9.58
Total conc. (4:1)	251	15.76	88.03

The oil film apparently has no beneficial effect, as the results are not quite as good as those obtained in tests 5, 6 and 7. The flotation concentrate in this test contained but 4.04 per cent silica.

Test No. 10.—This is given to show the results obtained on a wholly different ore. A high-grade telluride ore was crushed to 40-mesh and treated by flotation with reconcentration of the tailing on a Wilfley table:

	Weight grams	Assay Au. oz.	Assay Ag. oz.	Distribution Au. %	Distribution Ag. %
Ore taken, 40-mesh	500	39.74	10.00	....	...
Flotation conc. (14.7:1)	34	506.20	101.70	86.62	69.04
Wilfley conc. (31.25:1)	16	67.44	27.30	5.43	8.73
Tailings	379	4.68	1.80	8.91	13.62
Total conc. (10:1)	50	365.79	77.80	92.05	77.77

Summary of Copper Tests.

Treatment	Preparation	Recovery cu. %	Grade cu. %	Conc. ratio
1 Wilfley alone	Crushed 30-mesh	46.50	6.28	9.00
2 Flotation alone	Crushed 40-mesh	59.34	20.60	23.14
3 Flotation and Wilfley	Crushed 30-mesh	70.28	11.95	11.34
4 Flotation and Wilfley	Crushed 20-mesh	81.27	21.22	5.09
5 Flotation and Wilfley	Crushed 16-mesh	90.06	21.13	3.90
6 Flotation and Wilfley	Crushed 16-mesh	93.94	16.81	2.47
7 Flotation and Wilfley	Crushed 16-mesh	89.21	13.72	3.42
8 Flotation alone	Ground 16-mesh	66.49	23.02	5.54
9 Flotation and Wilfley	Crushed 16-mesh	88.03	15.77	4.00

These tests indicate that with particular ore possibly all the chalcopyrite would float. The fact that the tests do not fully bear out this belief may be accounted for by the accidents of manipulation in small tests.

Electrolytic Determination of Lead.

By Elmer List.

The Guess-Haultain electrolytic assaying outfit is a neat device for the rapid and accurate determination of lead in large and small amounts.

The accuracy of this method ranks with that of the most carefully made determinations by other methods and its great advantage is the small amount of the chemist's time required. In the presence of manganese or antimony it is necessary to have a large excess of free nitric acid in the electrolyte, under which condition neither element interferes. Bismuth, even in the presence of large amounts of free nitric acid, is partly precipitated as bismuth oxide with the lead. Its presence can be recognized by a light blue color given to the peroxide coat. Arsenic and tellurium must be removed before electrolysis, for if present they effectually prevent the deposition of lead.

Unless the anode is sandblasted, only a comparatively small amount of peroxide will adhere, but when properly sandblasted, adherent deposits of 250 mg. and even up to 600 mg. of lead peroxide may be obtained in daily work.

A weight of 0.855 mg. is advised in order to avoid the necessity of calculating each result, the weights of peroxide found being called lead. The theoretical factor is 0.866, but in practice 0.855 is found to be more accurate, probably due to an excess of oxygen in the peroxide.

The sample for analysis is weighted into a tall battery beaker of 200 cc. capacity, is digested with 25 cc. of nitric acid. The lead sulphate formed is readily dissolved after boiling, by the addition to the beaker of 25 cc. of a saturated solution of ammonium nitrate containing 25 per cent of free ammonia. This must be added carefully to prevent boiling over. After the solution is complete, the beaker is filled with warm water. The solution is now ready for electrolysis. A wide range of current strength is permissible, but from 1.5 to 2 amp. is the most satisfactory. This amount of current keeps the solution sufficiently warm during the electrolysis. At the end of two hours the anode is removed, washed in water, then alcohol, ignited and weighed.

When the amount of lead in the sample is small (below 0.5 per cent) not more than 5 cc. nitric acid must be present in the electrolyte to secure a complete deposition of peroxide. When more than 25 per cent of lead is present, 50 cc. of nitric acid is necessary to insure a hard, firm, and closely adherent coat. This deposit will not rub off nor crack if enough nitric acid has been used.

To clean the electrodes, they are placed in boiling nitric acid, in which some copper rods have been dissolved, for a few hours.

The electrodes are stationary and of two forms. The anode is shaped into a blade having an immersion area of about 50 sq. cm. and weighs about 1.5 grams. The blade is sandblasted and corrugated lengthwise. Strips of platinum foil form the cathodes. Three electrodes are used in each cell, one cathode on each side of the anode.

These electrodes are connected with slotted aluminum terminals, in which they are held by contact pressure. The terminals are 5/16-inch rods projecting 2 in. horizontally in front of the wall of the cabinet. Below the projecting rods are arranged suitable moveable shelves for holding the beakers during the electrolysis. At the back the anodes are connected with one pole of the current and the cathodes with the other pole.

This method fills the demand for greater speed and higher accuracy in making daily assays of products containing but a small amount of lead and has supplanted the older analytical processes.

Calculation of Furnace Charges—III.

By Regis Chauvenet.

The main object of this presentation of a "slag method" is to show how, from given materials, to compute a "required" slag of definite composition. Hence we do not go into lengthy discussions of the physical characteristics of various slags, nor of the conditions which make a certain type of slag desirable.

It is necessary nevertheless to recognize the fact that limitations are sometimes imposed by the composition of available fluxes, or of the ore itself, so a few remarks are appended to show how far it is safe to vary the composition, especially as to the limits between which the silica ratio may be varied, and to some extent the proportions which may be allowed of certain bases, and the ratio of the latter "inter se."

Iron.—Almost invariably the only addition for flux in the iron blast furnace is limestone. This may contain more or less magnesia, which, however, is not detrimental except under conditions as to alumina percentage to be presently specified. The ores of iron are low in slagging bases (other than iron), with the exception of alumina, and this, at many iron works is considered in the light of an acid.

Manganese presents no difficulties, the metal will usually be reduced in some measure, entering the pigmetal, another portion joining the slag of course in an oxidized condition. Discussion of the operations necessary for the manufacture of "spiegel" would lead us too far from the intent of this article.

As for lime and magnesia *in the ore*, they serve simply to reduce weight of the limestone to be added as flux.

We are not yet giving actual slag compositions, but may state that while it has been customary in the past to figure iron slags as pure silicates, it is to-day quite as common to assume a certain ratio as between "acid" and "base" and to take the sum of silica and alumina as the "acid." For details of this procedure in actual computations, see examples to follow.

In ordinary cases, with low alumina, the ratio of a singulo silicate may be safely followed, treating alumina as a base. Owing to limitations imposed by materials, little regard can be had to the proportions of the bases to one another, but one point should be noted, viz.: the danger of slagging off iron oxide. No superintendent of any knowledge or experience would incur such a danger, but a brief discussion of conditions which might lead to it may not be amiss. These are:

(1) Excessive silica ratio, especially when accompanied by imperfect reduction, say too low a fuel ratio.

(2) Deficiency in number of bases, as for instance an ore containing no bases except iron, and a limestone with lime only as base. This assumes absence of alumina, or an exceedingly low percentage of same in ore and fuel.

The first condition was sometimes found in the old-fashioned charcoal practice. It was a pet fallacy of many furnace men in former days that to increase the lime burden was to increase the consumption of fuel, and the cost of charcoal was by far the most important item in expense account. The reasoning, though fallacious, was simple, viz.: "The more you put into the furnace, the more you have to melt." This, to the uninstructed "boss" seemed axiomatic. That it might take more fuel to melt 100 lb. of refractory stuff than 150 of a fusible slag, probably never occurred to him. Some of the silica ratios in these furnaces were terrifying, and it is not surprising that the slags were often "deeply, darkly, beautifully green," or that they had to be mechanically pulled out of the "notch."

Lime silica is a highly infusible product. But aside from questions of temperature a chemical influence comes into play. Silica tends to form polybasic silicates, the general rule being that increase in the number of bases produces greater fusibility. Whether, with high temperature and powerful reduction an iron furnace could be made to yield a pure lime silicate slag, and put all the iron into the metallic state, may be an open question. I greatly doubt it. Certainly a case can be cited in which there was a ruinous percentage of iron in the slag, which was rectified by the addition of aluminous ore to the mix.

Broadly, the iron furnace slag (manganese aside) is usually composed of silica, alumina and lime, or in the case of magnesian limestone of these constituents plus magnesia. MgO (see above) is dangerous only when alumina is high. With alumina not much over 10 per cent, there is no danger. With MgO and Al_2O_3 both about 20 per cent, the slag may become viscous.

We here give two actual furnace slags, both typical of everyday running. Both are averages, but the variations from week to week were trivial.

	I.	II.
Silica	39.51	38.20 per cent
Alumina	10.82	7.85
Lime	30.94	41.06
Magnesia	6.58	11.84
	99.88	99.90

If the reader will take the trouble to "formulate" these slags as silicates he will find that they are each astonishingly near to perfect "singulo" formulæ. They have in fact been selected for that reason. But if we compare them on the basis of "$SiO_2 + Al_2O_3$" as acid, they differentiate.

It is the usage at furnaces using Al_2O_3 as an acid component, to bring their slags between the limits:

acid : base :: 1 : 1.5

and

acid : base :: 1 : 1

that is, the minimum of silica-plus-alumina should be 40 per cent, and the maximum 50 per cent. Usually, about 45 "acid" to 55 "base" or a ratio not far from 1 : 1.2, indicates average practice.

Our No. II conforms, as its ratio of "acid" to base is as 1 to 1.17 or 46.10 to 53.80 in percentages.

But No. I gives

$SiO_2 + Al_2O_3$ . . . 56.36 per cent
Bases . . . . . 43.52 per cent.

Ratio of acid to base is as 1 : 0.77. It cannot be said that No. I was as free flowing as No. II, but it was accepted as a good working slag.

The illustration serves to show that a far wider range is permissible for the ratio of the composite "acid," than for "acid" considered as silica alone. In fact the "oxygen ratio" is no longer much considered in the iron furnace.

"It is found in practice that the efficiency of slag varies more nearly with the basicity than with changes in the oxygen ratio." (Forsythe.)

Copper.—Slags from the copper furnace (matting) show wide variations, as it is usually impossible to make a slag of exact pre-arranged formula or percentage. In pyritic smelting there is a large margin, if only because we cannot always predict the amount of oxidation of the iron, (i. e., from FeS_2). According to the oxidation will be the ratio of slag to matte.

In stating as below the allowable variations in constituents of copper slags it should be remembered that manganese may be classed as iron, and barium and magnesium as calcium.

Slag constituents.	Minimum	Maximum.
SiO$_2$	26	45 per cent.
Al_2O_3	0	20 " "
FeO (MnO)	18	45 " "
CaO (Mg, Ba)	0	28 " "
ZnO	0	14 " "

Lead.—The following table of lead slags, showing percentage only, not formulæ, is taken, as is the above maximum and minimum statement for copper slags, from the late Howard van F. Furman's "Manual of Practical Assaying."

Typical Lead Slags.

No.	SiO_2	FeO	CaO	ZnO
1	35	28	28	
2	34	34	24	
3	34	34	17	7
4	30	40	20	
5	30	48	12	
6	28 30	54	6	

These do not sum to 100, an apparent anomaly to be later explained.

We shall use the "excess" method at first, and in addition

to fluxing problems give some illustrations in the application of stoichiometric principles.

(a) Ore has silica 40 per cent, alumina 20 per cent, as its only "slag" constituents. Calculate for slag on a "singulo" silicate basis (alumina as a base) having a limestone containing silica 10 per cent and calcium carbonate 90 per cent. Calculate on 100 lb. of ore.

Solution.—First find SiO_2 excess in the ore itself on the required basis. Alumina singulo silicate is $2\,Al_2O_3 + 3\,SiO$, stoichiometrically 204 : 180.

$$204 : 180 = 20 : 17.64 \quad SiO_2 \text{ required for } Al_2O_3$$
$$40 - 17.64 = 22.36 = SiO_2 \text{ excess in the ore.}$$

Next find CaO excess in the limestone. Enough CaO must be taken out of the limestone *to satisfy its own silica,* before we can compute for the ore. In other words, we must get the *lime excess* of the limestone and compare it with the *silica excess* of the ore. Under the given condition, the excess calculation must be for the singulo form:

$$60 : 112 = 10 : 18.66.$$

This 18.66 is lime (formulistically 2 CaO) required for the silica of the limestone.

Total lime in the limestone is $90 \times 0.56 = 50.4$ per cent. Then, 50.4 — 18.66 = 31.74 = excess of CaO or "available" lime.

The problem is now reduced to this, viz: "An ore with 22.36 per cent of silica is to be adjudicated as to a lime singulo silicate, with a limestone containing 31.74 per cent of CaO." For the alumina of the ore is out of the calculation, having been set aside with its proper amount of silica in the first operation.

Also, the silica of the limestone is out of this final computation, having been set aside with its calculated percentage of lime.

These quantities, being in their proper singulo ratios, do not in the least disturb the calculation of the remaining portion of the materials, nor do they affect the correctness of the outcome, since that must be in "singulo" form.

Thus we have now to do only with the excess SiO_2 on the one side, and the excess of CaO on the other. These are often called, as above, "available" quantities.

Our proportion will be:

$$SiO_2 : 2\,CaO = \text{excess silica} : \text{required CaO}$$
$$60 : 112 = 22.36 : 41.74$$

The only remaining question is: "How many pounds limestone containing 31.74 per cent available CaO will furnish 41.74 lb. CaO?"

$$31.74 : 100 = 41.74 : 131.5$$

It will then require 131.5 *lb. of the limestone* to satisfy 199 lb. of the ore.

This as an initial type excess problem, has been detailed at great length. In future certain steps, i.e., those always involved in similar cases will be taken for granted.

(b) What will be the percentage analysis of the slag from problem (a)? Assemble the constituents from 100 lb. of ore and 131.5 lb. limestone.

	SiO_2	Al_2O_3	CaO
From 100 lb. ore.....	40.00	20.00	..
From 131.5 lb. limestone.....	13.15	.....	66.27
	53.15	20.00	66.27

Weight of slag for 100 lb. ore = 139.42 lb. Analysis:

$$SiO_2, \frac{5315}{139.42} = 38.12 \text{ per cent}$$
$$Al_2O_3, \frac{2000}{139.42} = 14.34 \text{ per cent}$$
$$CaO, \frac{6627}{139.42} = 47.53 \text{ per cent}$$
$$99.99 \text{ per cent}$$

Arithmetical Excess.

In the above example we have assumed that "excess" meant excess above a given chemical ratio, but it is very frequently used to denote a difference between acid and base derived by simple subtraction without any reference to chemical adjustment. In fact, if the requirement for the slag is purely numerical, the handling of the "excess" is reduced to the same basis. In iron furnace practice the requirement is sometimes no more than ratio of "acid" to "base," which greatly simplifies the problem.

In the following problem we adopt what has become a common usage. The "oxygen ratio" is discarded entirely, and the sum of SiO_2 and Al_2O_3 is considered as the "acid" side of the slag. All other bases are simply added together without any regard to chemical ratio. An arithmetical ratio, acid to base, as stated above, from 1:1.5 to 1:1 is assumed. In the present case we use an intermediate figure.

(c) Analyses of the materials.

	Ore.	Coke.	Limestone.
SiO_2	4 per cent	4 per cent	5 per cent
Al_2O_3	2 per cent	1 per cent	2 per cent
MgO	4 per cent	.....	2 per cent
CaO	.....	.....	50 per cent
Fe_2O_3	90 per cent	.....	.....

Consider $SiO_2 + Al_2O_3$ as "acid"; CaO + MgO as "base."

Requirement.—Slag to contain 45 per cent acid and 55 per cent base. This being very close to the ratio of 10:12, let us adopt that ratio as the basis of calculation.

Figure separately on ore and coke, as usual at iron works, i.e., state what "stone" is required for 100 lb. of ore and for 100 lb. coke. The reason for the usage is found in the variant fuel ratio of the furnace. By having a stated weight of "stone" for ore and fuel we avoid the necessity of recalculation for a change in the fuel ratio.

Preparation of the Data.—In the *ore* the only "base" is MgO, 4 per cent. Acid is 4 + 2 = 6 per cent.

$$12 : 10 = 4 : 3.33 = \text{acid required by MgO}$$
$$6 - 3.33 = 2.67 = \text{acid excess in the ore.}$$

Coke.—Acid excess is 4 + 1 = 5.

Limestone.—Base 52 per cent, acid 7 per cent.

$$10 : 12 = 7 : 8.4 = \text{base required by its } SiO_2$$
$$52 = 8.4 = 43.6 = \text{basic excess.}$$

This completes the preliminary calculations. We are now to find:

(1) "Stone" required by the ore:

$$10 : 12 = 2.67 : 3.2 = \text{required base.}$$
$$43.6 : 100 = 3.2 : 7.34 = \text{required limestone.}$$

(2) "Stone" required by the coke.

$$10 : 12 = 5 : 6 = \text{base required.}$$
$$43.6 : 100 = 6 : 13.67 = \textit{stone required.}$$

Proof.—Let us assume any fuel ratio, for illustration, and then compute total slag. If the latter proves to have the composition:

$$\text{acid} : \text{base} = 10 : 12$$

the proof is complete. Let ore to charge = 1000 lb., coke = 700 lb.

	$Al_2O_3 + SiO_2$	CaO + MgO
In 1000 lb. ore.....	60.00 per cent	40.00 per cent
In 73.4 lb. "stone"..	5.14 per cent	38.17 per cent
In 700 lb. coke.....	35.00 per cent	.....
In 96.32 lb. stone....	6.74 per cent	50.09 per cent
	106.88 per cent	128.26 per cent

$$106.88 : 128.26 = 10 : 12.$$

In the above proof table the figures derived from the stone are simply products of the pounds "required" by the respective percentages as per analysis. For instance, 100 lb. coke required 13.76 lb. stone, then 700 lb. requires $13.76 \times 7 = 96.32$, and this multiplied by 0.7 and 0.52 respectively gives 6.74 and 50.09.

In order to simplify the above example, nothing was said as to subtraction of silica to provide for silicon in the pig metal. This which is a very simple matter, will be shown in the next problem. In this we return to the "formulistic" requirement.

(d) Analyses of ore, stone and fuel:

	Iron Ore.	Stone.	Coke.
SiO_2	8.00 per cent	6.00 per cent	8.00 per cent
Al_2O_3	5.00 per cent		
MgO		6.00 per cent	
CaO		40.00 per cent	
Fe_2O_3	87.00 per cent		

Assume ore 100 lb, coke 70 lb. Figure for the stone required to make a singulo slag. Alumina figured as a base.

These are slightly simplified analyses from an actual case. The coke ash was not pure silica, but is so assumed to remove some complication from the problem.

The subtraction of silica from the ore prior to computing the slag is, as regards its amount, a somewhat arbitrary proceeding, as the per cent of silicon in the pig metal varies according to the heat and reducing power of the furnace. We shall in this case assume that 3 per cent of the silica will be reduced to silicon, that is, we shall figure on 5 per cent of silica in the ore instead of 8 per cent, leaving silica in the coke and stone as in the analyses.

The singulo formulæ are $2\,Al_2O_3,\ 3\,SiO_2$; $2\,CaO,\ SiO_2$ = and $2\,MgO,\ SiO_2$.

Under the conditions no set ratio between the bases is possible. As we have taken 100 lb. of ore, figures will indicate either pounds or percentages.

Use the formula in all the proportions and *nearest whole numbers* for the atomic weights.

(1) Take out alumina silicate from the ore.

$$2\,Al_2O_3 : 3\,SiO_2 = 204 : 180 (= 17 : 15) = 5 : 4.412$$

Pounds SiO_2 required by alumina = 4.412. Sum up all the SiO_2 in ore and coke, and subtract 4.412.

SiO_2 in ore (8 − 3)	5 lb.
SiO_2 in coke	5.6 lb. (8 per cent of 70)
SiO_2 in ore and coke	10.6 lb.
Less required by Al_2O_3	4.412
SiO_2 available for stone	6.188

(2) Find excess of CaO in the stone. We have 6 per cent MgO in the stone;

$$2\,MgO : SiO_2 = 80 : 60 (= 4 : 3) = 6 : 4.5$$

That is, the MgO requires 4.5 per cent SiO_2. Silica in the stone is 6 per cent; subtract the 4.5, remains 1.5 per cent SiO_2 to be set against CaO. In order to bring CaO into the last term put SiO_2 first.

$$SiO_2 : 2\,CaO = 60 : 112 (= 15 : 28) = 1.5 : 2.8$$

We might also have figured MgO and CaO in one operation by using factor $1.4 \times$ MgO.

(If it had happened that there was *not enough* SiO_2 to satisfy the MgO, the excess of MgO would have been added to the available (total) lime.)

We now have 46 − 2.8 = 43.2; that is, our "stone" has 43.2 per cent *available* CaO.

(3) Now we bring together the ore and the limestone, with their respective excesses. Since we are figuring on 100 lb. of ore, and seeking required stone, we put the SiO_2 excess first in the proportion:

$$SiO_2 : 2\,CaO = 60 : 112 = 6.188 : 11.551$$

Available CaO called for is 11.551 lb., hence,

$$43.2 : 100 = 11.551 : 26.738 \text{ limestone.}$$

Answer.—100 lb. ore requires 26.738 lb. limestone.

The decimals have been carried far beyond any practical necessity.

It remains now to assemble our figures and check up. Analysis of the slag may then be figured.

(4) Take 100 lb. of the ore, 70 of coke and 26.738 of "stone"; figure out actual pounds of each constituent. As this will give us total weight of the slag, the latter may then be figured in percentage, i.e., its analysis may be stated in advance.

	SiO_2	Al_2O_3	CaO	MgO
In ore	8.00	5.00		
In stone	1.604		12.30	1.604
In coke	5.60			
	15.204	5.00	12.30	1.604

Weight of slag per 100 lb. ore charged = 31.108 lb. Analysis:

SiO_2	39.23 per cent
Al_2O_3	16.07 per cent
CaO	39.54 per cent
MgO	5.15 per cent
Total	99.99 per cent

We shall now give a problem in which the data require some simplification before computing. Before doing so we should point out that the substitution of one base for another by means of one of the "factors" already detailed in Article II *does not affect the excess as figured from the analysis.* This is a priori evident to anyone to whom the stoichiometric relations have become familiar, but we here give a case in proof.

We have a limestone, CaO, 39 per cent; MgO, 9 per cent. Since MgO : CaO = 40 : 56 = 1 : 1.4 we can say $9 \times 1.4 = 12.6$; call this CaO and add it to the actual CaO: 39 + 12.6 = 51.6.

Now suppose the stone contains in addition to these bases 10 per cent silica.

Figure on basis of a singulo, and find basic excess of the stone. First take it as it stands i.e., without the transformation of the MgO.

$2\,MgO : SiO_2 = 80 : 60 (= 4 : 3) = 9 : 6.75 = SiO_2$ required for MgO 10 − 6.75 = 3.25 = SiO_2 left for CaO.

$SiO_2 : 2\,CaO = 60 : 112 (= 15 : 28) = 3.25 : 6.07$ = CaO for the SiO_2.

Total CaO less required by SiO_2 = 39 − 6.07 = 32.93 = *net excess.*

Now make the change of MgO into CaO, by using factor as above, we get total CaO = 51.6. Figure excess CaO in the regular way:

$SiO_2 : 2\,CaO = 60 : 112 = 10 : 18.67 = CaO$ required by SiO_2. 51.6 − 18.67 = 32.93 *i.e., precisely the former figure.*

(e) In our slag problem preceded by simplification, suppose an ore to analyze as follows:

SiO_2	36.3 per cent
FeO	16.0 per cent
MnO	5.9 per cent
CaO	5.6 per cent
MgO	4.0 per cent
S	5.1 per cent
As	0.6 per cent
Pb	18.0 per cent
Cu	4.4 per cent
CO_2 and O	4.1 per cent
Total	100.0 per cent

The "flux" is an iron ore containing:

SiO_2	4.00 per cent
FeO	86.00 per cent

(The analysis would, of course, show Fe_2O_3, but this is reduced by the ratio of 10 : 9 to FeO for slag computation.)

We are to produce a *bisilicate* slag after clearing of matte and adjusting bases. Use 100 lb. ore as unit weight. Find weight of the "flux" to be added. Find weights and analysis of matte and slag.

(1) Copper in the matte:

$Cu_2 : S = 4 : 1 = 4.4 : 1.1 = S$ for Cu_2S.

weight of $Cu_2S = 4.4 + 1.1 = 5.5$ lbs.

(2) S remaining is 5.1 − 1.1 = 4 per cent. Take out FeS to the extent that this 4 per cent permits:

S : FeO = 32 : 72 = 4 : 9. FeO taken for matte 16 − 9 = 7 per cent (lbs.) FeO remaining (for slag calculation). FeS in the matte = 4 lbs. S + 7 lbs. Fe = 11 lbs. FeS.

(3) Take out As and Fe as Fe_5As (speiss):

As : 5FeO = 75 : 360 (= 5 × 24) = 0.6 : 2.88.

FeO finally remaining for slag is 7 − 2.88 = 4.12.

Note.—It is useless if the analysis states the iron as FeO to reduce this to metallic iron in calculating out S and As. Take the equivalent amounts (molecular weights) of the compounds given by the analysis. As this may not be at once evident, we step aside for a moment to explain.

Take out the As in the ordinary way, viz.:

As : Fe_5 = 75 : 280 = 0.6 : 2.24.

That is, metallic iron required = 2.24 per cent. But we would now have to convert this into FeO so as to subtract, viz.:

Fe : FeO = 56 : 72 = 2.24 : 2.88.

This 2.88 is precisely the figure already obtained directly.

This is very elementary; but it is by no means uncommon to see just this "round the corner" way of calculating through lack of familiarity with the language of symbols.

The speiss weights 0.6 + 2.24 lb = 2.84 lb.

To resume the calculation:

(4) Reduce the bases to two groups, i. e., FeO and MnO in the one, MgO and CaO in the other.

FeO : MnO = 72 : 71. We do not regard this ratio, but call it equality, i. e., we simply add residual FeO to the MnO : 4.12 + 5.9 = 10.02. This we shall enter as 10 per cent

MgO is 4.4 × 1.4 = 5.6 = nominal CaO.

Total CaO = 5.6 + 5.6 = 11.2 per cent to be reckoned as CaO.

We have thus "prepared" the ore for calculation. Whatever flux is to be used can now be computed.

The Cu, S, As, are disposed of. The Fe has been accounted for to the extent rendered necessary by the residual S and the As. The lead, under the supposition of its complete reduction, is out of the computation. Basis are ready for adjustment to silica.

Remains for calculation:

SiO_2	36.3 per cent
FeO group	10.00 per cent
CaO group	11.2 per cent
Lb. to be reckoned in slag	57.5 per cent or lb.

These, however, are not altogether "actual" pounds, since the 4-lb. MgO has become 5.6 lb. CaO. These and the lb. of FeO are the *chemical equivalents of pounds* in the special relation into which they are now to be brought with fluxing material. As we have twice gone into the detail of similar adjustments, we here indicate operations in outline:

Ore. SiO_2 required by its own CaO..... 12.00 lb.
SiO_2 required by its own FeO..... 8.33 lb.
20.33 lb.

36.3 − 20.33 = 15.97 = "available" SiO_2.

Iron flux. FeO required by its own SiO_2 = 4.8 per cent leaves 81.2 FeO "available."

Final adjudication:

SiO_2 : FeO = 5 : 6 = 15.97 : 19.16 = FeO required by SiO_2 in the ore.

81.2 : 100 = 19.16 : 23.6 = *weight in lb required of the "flux."*

The slag, leaving out of account the difference in weight caused by substitution of 5.6 nominal CaO for 4 lb. actual MgO, figures out as follows:

SiO_2 from ore	36.30		
SiO_2 from flux	0.94	Total SiO_2	37.24
FeO from ore	10.00		
FeO from flux	20.30	Total FeO	30.30
CaO from ore			11.20
Weight of slag per 100 lb. ore			78.74

Analysis of the slag:

SiO	47.3 per cent
FeO	38.5 per cent
CaO	14.2 per cent
	100.0

Matte and Speiss

	Weight, lb.	Per cent
Copper	4.40	22.75
Iron	9.24	47.77
Sulphur	5.10	26.37
Arsenic	0.60	3.10
	19.34	99.99

We have tacitly assumed that all the sulphur and all the arsenic would be found in the matte. Any pre-established rate of loss, as derived from experience, should, of course, be subtracted in the first place as a part of the "preparation" for computation.

The cases so far given which can be worked from either a formulistic or percentage bases by "excess" are of a very simple type. They regard in either case nothing but the ratio of silica (or "acid" $SiO_2 + Al_2O_3$) to base, and do not bring in any requirement as to the quantitative relations of basis among themselves.

Moreover, the complexity introduced by the use of two fluxes, usually an iron oxide and a limestone, has not been touched upon. As a general problem the requirement of a specific relation between the bases (or basic groups) cannot be met by the use of one ore and one flux.

Example. An ore, an "iron flux" and a limestone have the following analyses (slagging constituents only in the ore):

	Ore.	Iron flux.	Limestone.
SiO	40	10	5
FeO	10	80	
Bases	5	(CaO)	50

Suppose the slag requirement to be:

SiO_2	40 per cent
FeO	40 per cent
Bases	20 per cent

We see that the relation between silica and bases in the ore, though the FeO and base have been purposely set in the required ratio of 2 : 1, gives an excessive silica ratio. It is hardly necessary to demonstrate by figures that we cannot use either the ore and the "flux," or the ore and the limestone, and get a mixture for the required slag. If, by means of the ore and the iron flux we equalize SiO_2 and FeO, we drop the "base" far below its required figure, and it would be equally impossible to use the "stone" alone under the conditions of the problem.

Upon attempting the use of all three, calculating by the method of excess, we see that the solution is possible only by trial and readjustment.

Into this procedure we do not go, since by the method to be presented this and similar problems are solved directly and far more easily.

We shall, in fact, present a direct solution of the complex case:

	Ore.	Flux.	Limestone.
SiO	a	b	c
FeO group	d	e	f
CaO group	g	h	i

the case, namely, where all three of the materials on hand contain each and all of the constituents to be computed.

The computer in such a case, using "excess," would conclude that he had a problem on his hands "more curious than useful."

It is not impossible, but it is tedious and useless, to adopt a difficult method when an easy one is at hand.

Denver, Colorado

Symposium on Research

A JOINT meeting of the New York Sections of the American Electrochemical Society, the American Chemical Society and the Society of Chemical Industry was held in the Chemists' Building, New York City, on Feb. 9. The meeting, which had been arranged by the New York Section of the American Electrochemical Society, was devoted to a symposium on research.

The chairman of the Section, Mr. ELMER A. SPERRY, referred in his introductory remarks to the difference between accidental discovery and invention as the result of research and pointed out the industrial results of Faraday's research work. For research a true pioneer spirit is necessary—the desire, coupled with inspiration, to tackle something that is difficult, something that seems impossible. Nothing else is worth while.

Five papers were then presented by Messrs. Lidbury, Comey, Bennie, Lindsay, and Coolidge, which are given here almost in full.

Research in the Small Factory.

Research as a Gamble

Mr. F. A. LIDBURY, of the Oldbury Electrochemical Company, of Niagara Falls, N. Y., pointed out that in spite of the modern tendency to the aggregation of industrial processes into units and combinations of enormous size, it still remains a fact that a very considerable proportion of industrial operations are conducted by organizations which are small.

The admiration of the modern large industrial organizations has led to attempts to model such small organizations as miniature imitations of the large ones without due consideration being paid to the fact that the needs of the two classes may be and almost always are entirely different. To mention but one instance, whereas in a large organization it is possible to draw up a perfectly definite staff chart in which duties of a specialized character are assigned to each member, in a small organization it is usually the case that duties of a very diversified nature have to be assigned to one and the same individual.

"In such cases there can be no question of a certain position carrying with it perpetually absolutely definite duties, for it may not be possible to find an individual whose training and abilities would qualify him for the exact diversified duties of the man whom he replaces; this necessitates a much looser and more fluid form of organization in which the important question is how best to divide up all the duties to be performed among the staff; and it is clear that a change of personel will frequently involve a change in the distribution of responsibilities and duties.

"Now it will be found that this difference between the two types of organization extends even to the organization of research. Classical examples of the organization of large research departments are known to us, and several have been excellently described; but here, again, we usually have a system built up of highly specialized units. I am inclined to think that there is possibly too great a tendency to assume that the admirable and remarkably successful systems of such organizations ought to be imitated as far as possible when it comes to doing research work in a smaller aggregation, but if it is borne in mind that the essential feature of these systems is the high specialization of the unit, it is obvious that when we come down to cases in which research has to be conducted by two or three, or even one man, we are dealing with an entirely different kind of condition and too slavish imitation will lead us at once into serious difficulties.

"The suggestion I have to make is that as differentiation becomes a virtue in proportion to the size of an organization, so integration becomes a virtue in the smaller type of organizations. You cannot in such cases afford a large staff of research men, each equipped to fit his own special position in a large machine; you have instead, one, or perhaps two or three men, and in such cases it is the more necessary that their training be such as to broadly equip them for technical investigation. Bearing this in mind, it becomes obvious that the smaller the number of research men the more important it is to avoid anything like a sharp separation of the research department. Such men must be not only investigating chemists, they must be thoroughly familiar with the technique of commercial operations; they must have no little practical experience of chemical engineering; they must, above all, have rid themselves of the habit of thinking in test tubes and of the unthinking worship of laboratory accuracy and scientific efficiency, and be able even in their laboratory work to constantly bear in mind the conditions of its translation to a large scale and of the commercial as well as the scientific significance of their results. They must, in other words, have that type of experience which enables them to tell when, for instance, additional scientific efficiency is likely to make an increase rather than a decrease on the cost sheet. All this is not likely to be found in a man straight from college, nor is he ever likely to acquire it if immured in a sort of holy of holies called a 'research laboratory.'

"I am well aware that research can be regarded as a method, and that a man who has grasped that method by his scientific work at college ought, if given proper opportunities, to be able to apply it in technical work once he learns to realize that while the form of his equations is the same, some factors are different, and others have quite a different significance.

"Research may, indeed, be 'a habit of thought,' but, then, so is the faculty of mathematical analysis, and I have never learned of any well-authenticated case of a man 'sitting in' at a game of poker with only this faculty and without experience of the game and getting much satisfaction. Indeed, this analogy does not seem to me to be much too extravagant; commercial research is very much of a gamble in any case; you put in your money and you don't know what you are going to draw, if anything; and it certainly seems as though to entrust the work on which the progress of an industrial concern depends to a man insufficiently familiar with technical operations and the factors in the equation of economy, somewhat resembles staking a mathematical professor of presbyterian descent in a crowd of professional sharpers. His experiences may be interesting and varied; he might even be able to gather from them enough material for a very important paper 'on some remarkable divergencies from the theory of probabilities,' but it is highly improbable that the commercial efficiency of his labors would be very high.

"It will be perceived that in the large model research organization such considerations need not enter. Specialized as the individual members may be, the department, as a whole, possesses, or has available, the necessary machinery for co-ordination. The segregated research man has, on the contrary, to possess within himself nearly all the elements of such co-ordination. If he is kept, or keeps himself, out of touch with practice, what is he to do? He is up against a stone wall.

"Nor it is obvious why we cannot carry this line of argument to its logical conclusion. This involves the proposition that there should be no separate research department in the small factory; that research in such cases should be done by chemists to whom is assigned as a regular part of their duties the supervision of and the responsibility for some part or parts of the plant.

"This probably sounds extreme. Of course, it is not ideal, but then the organization of a small plant is always a compromise. The problem is to make it as successful a compromise as possible, and I firmly believe that two chemists devoting part of their time to supervision and part to research will produce results at least equal in quantity and exceeding in quality those which would be produced by the same two men if one were kept entirely on supervisory work, and the other entirely on research.

The disadvantages attaching to discontinuous research may be readily admitted, but if the load-factor of research so carried on is obviously low, its efficiency is remarkably high. The danger of segregated research is that so much of it, though scientifically interesting, is technically worthless and consequently practically waste of time; and just as the technical analyst learns to confine his work to the limit of accuracy necessary in each particular case, so it becomes second nature with the technically experienced research chemist to limit his inquiries in a corresponding way. The amount of time saved is just as startling as in the case of analytical work, and this more than counterbalances the disadvantages of the bad load-factor referred to above.

"I do not want to be construed as underestimating the value of purely scientific knowledge and training in these matters, but in academic circles at least the fact is too often lost sight of that in the majority of important technical discoveries, theory springs from practice, and the practice arises first empirically. A Baekeland, for instance, synthesises a new plastic, works out methods of manufacture and applications; then as an afterthought, and presumably to salve his scientific conscience, he investigates the formula and decides that the substance is oxybenzyl-methylene-glycolanhydride. An Acheson discovers and works out a method of incorporating lubricating graphite in liquids; five years afterwards he discovers that he is dealing with a colloidal suspension. These instances are purely typical.

"Complaint is frequently made that research does not get a chance in the small factory; that it is difficult to get it introduced, and that when introduced, the research man is apt to have an altogether bad and discouraging time of it. So far as these complaints are grounded, they are probably due to the evil results of segregation. For this the manufacturer is not to be blamed so much as the chemist, and, in particular, the trainer of chemists. In these matters, the manufacturer who does not know is pretty apt to do what he is advised, and the tendency among a certain type of professor to glorify research as a kind of nostrum of a very superior character quite in a class by itself and in no way to be confused or mixed with routine has its natural results not only on the manufacturer, but, unfortunately, also on the student, who, not infrequently, is given the impression that a factory is merely a hot-bed of inefficiency and that he can step right in and by the use of his scientific training produce immediate and miraculous results. This is not at all a habit of mind conducive to success.

"The student on coming into contact with technical work must discover sooner or later that there are usually good reasons for things as they are and that it is infinitely more difficult to carry out a piece of research to a successful technical and commercial conclusion than to carry out a piece of research to a successful scientific conclusion. If this were impressed upon him previously it might save him a few, at any rate, of the jolts he is bound to get in practice. The manufacturer, on the other hand, should be impressed not so much with research as a scientific cure-all, as with research as a habit of thought to be introduced in the most intimate relation to daily practice. As things are, whenever a small concern boasts that it conducts a *separate* research department, it may be pretty confidently guessed that that research department is not paying cent for cent on its running expenses.

"One more word in regard to the efficiency of research in such a factory. It is too often the case that money spent in salaries fails to bring in its due return in work on account of the insufficiency of facilities provided. No doubt much excellent work can be done with makeshift apparatus, and no doubt, again, if a good library is not available in a works references can be hunted up somewhere else.

"But in commercial research more than in any other, time is an important factor; and it is astonishing that in so many cases a concern will employ not one, but two or three investigating chemists at good salaries and then stint them in regard to the supply of books and special apparatus. This again, I imagine, is a case where the manufacturer is doing just as he is told. He has been impressed by the reiteration that money spent in investigation will bring in rich rewards, but his informer has neglected to impress upon him that inadequate or insufficient equipment in the laboratory or works library is just as destructive of efficiency as in the factory itself."

Certain Phases of Technical Chemical Research.

Organization of Research of the du Pont Powder Co.

Dr. ARTHUR M. COMEY, chief of the Eastern Laboratory, at Chester, Pa., of the E. I. du Pont de Nemours Powder Company, presented a paper on "certain phases of technical chemical research."

Twenty-five years ago there was hardly a manufacturer who pretended to have any chemical control of works' operations, not to mention the question of research, and some of the most important purely chemical industries did not employ even a single trained chemist. "Of late years this condition has greatly changed. The causes for this great development in chemical research laboratories connected with technical operations are undoubtedly complex.

"One cause, however, which has contributed greatly to this change is the enormous increase in capitalization of various manufacturing industries, making possible the expenditure of considerable sums on laboratories, both in equipment and personnel, and they have found that the establishment of research laboratories on a large scale has been a profitable venture, where as a small laboratory employing one or two chemists in research work may prove far from a saving investment.

"The fact must not be overlooked that research laboratories will be maintained for any considerable length of time, as a part of the manufacturing cost of a chemical industry only when they show a real or supposed pecuniary profit. A laboratory may be maintained in isolated cases for a shorter or longer time when the results obtained therefrom do not pay; but the solid foundation for the continued maintenance of a research laboratory rests on the fact that its operation directly or indirectly increases the profit in the industry with which it is connected.

"Manufacturers have been discovering within the last few years that large research laboratories do increase their profits and hence such laboratories are being erected in increasing numbers.

"The problem for the small manufacturer is a different one, and many plans have been devised by which he may avail himself of the benefits to be derived from the investigation of problems connected with his industry, without the necessity of establishing a large research laboratory. The usual way to go about this has been for the manufacturer, when he has become convinced that a little research work would help his business, to employ a chemist, just graduated from college, and provide him with a wholly inadequate laboratory, for neither he nor the young chemist has usually any idea of what is necessary in the matter. He then sits back and waits for results.

"When, at the end of a few months, he not only has not profited several hundred per cent on his research investment, but probably sees no return at all, he is very apt to give the whole matter up and feel that research work in his business at

least is a failure. If he had employed a chemist who had already been trained in a large industrial research laboratory and had provided him with the necessary equipment and had enough confidence in him to wait a reasonable time, it is, in my opinion, most certain that results would have been obtained which would warrant the outlay. It is almost impossible, however, that the necessary confidence could be inspired by the ordinary graduate fresh from college.

"The situation has been handled recently in a different way by the establishment of industrial fellowships or scholarships in certain of our universities. This scheme has its advantages in removing the necessity of permanently equipping a laboratory, and is undoubtedly more economical as far as the first outlay is concerned. When a comparatively small definite problem is to be worked out, it may be the best solution, but there are many difficulties in the way of extensive use of this manner of industrial research. The difficulty of making sure that the manufacturer who establishes the fellowship should have the whole benefit of the work being not one of the least.

"Another serious difficulty in the establishment and continuation of a system of fellowships in a college under one head would arise if the number of these fellowships should become large. The manifold details of the operations involved in each industry which it is necessary for the investigator to understand before he can undertake intelligent research work in that industry would eventually become too overwhelming for any one person to grasp, but it is the plan, as I understand it, that the instructors in charge of the department of the college to which these fellowships are attached should oversee and direct the work of the men engaged in the actual research, for they are not supposed to be qualified to undertake the research without such direction."

Dr. Comey then gave an interesting description of the very highly developed organization of research work in the E. I. du Pont de Nemours Powder Company.

"The chemical work of this company is brought together under control of the chemical department. This department occupies the same important position in the company as that held by the engineering department, which has charge of all construction work carried out by the company, and all chemical operations of the company are controlled ultimately by the chemical department. The chemical director occupies a similar position in the organization of the company as that held by the director of the chemical work in the large German companies like the Badische Anilin & Soda Fabrik, for instance. This is unique in American industry.

"The work of the chemical department is carried on under three distinct divisions. The first division takes charge of those investigations which are made on problems which cannot well be studied in the laboratory. The direction of this work is centered in the main office of the company at Wilmington under one head chemist. In this division are experts on all the various manufacturing activities of the company, nitroglycerine, nitrocotton, sulphuric acid, nitric acid, etc. These are chemists who have usually been trained in our research laboratories and are engaged in making exhaustive studies on the efficiency of our works operations. These men have their headquarters at the main office of the company, but often spend long periods of time at the works themselves, where they are assisted by other chemists especially detailed for this work.

"Besides the chemists in this division there is a force of chemists who carry on the routine work of the works laboratories. Each one of our works is equipped with a works laboratory, whereby a close control of works operations is maintained. The chemists engaged in this work are under the control of the superintendents of the various works.

"There is a total of about 250 *trained* chemists in the employ of the du Pont company.

"A second division of the chemical department is known as the Experimental Station. This comprises a laboratory or rather a group of laboratories where research work is carried on on problems connected with the manufacture of smokeless powder and black powder; also, problems which are brought to the company from outside are studied here, and from the results obtained the company is in a position to gauge the true value of any process that may be offered them.

"The Eastern Laboratory forms the *third* division of the chemical organization, and at this laboratory only problems connected in some way with high explosives are investigated. Under the term "high explosives" are comprised all explosives except black powder and smokeless powder. The term 'dynamite' is generally applied to these explosives, but dynamite is a much more comprehensive term than is ordinarily understood by those not acquainted with the explosive industry. The du Pont company, for instance, manufactures at least fifteen different and distinct kinds of dynamite, and of each kind many grades, sometimes as many as ten, representing different strengths—but the point I wish to emphasize is that the work to which the Eastern Laboratory is devoted concerns not one of the greatest industries in the country, like steel or oil, but one of the lesser industries, and only a branch at that—but in spite of this, it has been found to be a distinctly profitable undertaking to maintain a research laboratory on a decidedly large scale.

"The laboratory organization at the present time is made up as follows: A director, and assistant director, and 25 trained chemists; by trained chemists I mean men who have taken a regular chemical course at a college or scientific school. Among these chemists are several who have taken the degree of Ph.D. here or in Germany. This makes, with the directors, 27 chemists. Besides these, we have a professional photographer, whose whole time is devoted to the work of the laboratory, and an office force of six men, including a chief clerk, file clerk, storeroom keepers and stenographers. In addition to the above force we have about 50 men on our payroll, making over 80 in all. This list includes three carpenters, three plumbers and pipefitters, etc., but the majority of these men are ordinary laborers, whom, however, we have trained in many cases to make routine tests, etc.

"All the above force is engaged directly or indirectly in the investigations which we are carrying on. The director and assistant director are responsible for the work turned out in the laboratory, but in order to get the best results it is our policy to place a large amount of the direct responsibility upon the chemist who is actually carrying on the research. I believe in this way the best results can be accomplished. The chemist becomes vitally interested in his work when he knows that *he* is responsible for his results, and in this way the net result to the laboratory is the combined effort of several brains rather than the thoughts of one brain, executed by another's hands. I believe it is of the utmost importance in order to obtain the best results to make a chemist feel that the work is *his* to carry out: that *he* is responsible for the results, and that *he* will receive credit for the results of his work. This cannot be effected if more or less minute directions are given for the details of a resarch.

"Naturally, it is imperative, under this policy, to have first-class men, but I believe that the best results can be obtained in a research laboratory only with first-class men. Men to whom cannot be trusted the development of a research should not be employed in a research laboratory to carry on researches.

"Now, I do not wish to convey the idea that as we have 25 chemists working on research work we have 25 independent workers or 25 lines of research carried out simultaneously. As a matter of fact, we have about 10 lines of research at the present time, and the men conducting these researches have a number of other chemists to help them in their work. The number of these chemists varies according to the conditions. In some cases it is not necessary for the chemist to have any aid outside of that from the workmen. In other cases there is a large amount of analytical and testing work to do in con-

nection with the research. One of the head research chemists, for instance, has four other chemists working for him. They are under his direction, and only indirectly responsible to the directors of the laboratory. These men, as I said, perform the necessary analytical work and tests connected with the research in question, and beside these chemists it is our policy to furnish all the laboring men that the research chemists can profitably employ in their work.

"This becomes especially important in certain lines of work, as, for instance, the development of a new process in the laboratory. In most cases of this kind we try the proposed process out on a purely laboratory scale with ordinary laboratory apparatus. If the first results are promising, we may set up a larger apparatus in the laboratory, and then proceed to erect a small experimental plant where the same kind of apparatus is used as is proposed for actual works operations, but on a smaller scale; for instance, experiments on the nitration of glycerine are first carried out in a small laboratory where 40 grams is used as a charge. Then the operation is repeated at our experimental nitroglycerine plant, where we make about 90 lb. of nitroglycerine to a charge, instead of many hundred pounds, which is the regular works' scale; but all the apparatus at our small plant is of the same material and practically the same model as that used for actual manufacture.

"This development of a process on a semi-manufacturing scale together with the nature of the investigations and their connection with explosives leads to the necessity of providing a large number of buildings for our work. We have at the present time 76 buildings, spread over about 50 acres of ground, in use in our work at the Eastern Laboratory. The majority of these buildings are of considerable size, and it is customary to carry on only one process or perhaps part of a process in any one building.

"The economy of the plan of developing processes to a manufacturing scale under laboratory control is obvious to anyone who has had to do with experimenting at a plant on works' scale. We use our workmen for running these small plants, under the supervision of the chemist who is developing that particular process, and these men often go over to the works when a manufacturing plant is erected for the completed process and are well trained for operating it.

"This plan also helps to keep us in close touch with works operations, which is a most essential condition in order to make the results of laboratory work most available.

"The younger chemists working on the research work under the older men are also being trained, and as the work increases, or our older men are promoted to other positions, they in turn become independent workers, *if* they are capable of doing such work, which we are able to judge during their term of training. This furnishes a very efficient method for procuring men best adapted to the work to be undertaken.

"Another incentive offered to our chemists to exert their faculties to the utmost is the form of bonuses for unusually meritorious work. This plan, by the way, extends to all employees of the company. Each year men who have accomplished some definite result, such as invention and development of a new process, or have accomplished results in any form which has brought valuable returns to the company, are awarded bonuses in the form of a certain number of shares of the common stock of the company, 5, 10, 15, 20 or more. This stock is not presented to the beneficiaries directly, but they receive the dividends on the same from the date of award. The stock is held by the company and a certain percentage is credited to it annually by a system based on the earnings of the company. By this system the stock is paid for in a few years, when it is turned over to the recipient without restriction. If he leaves the employ of the company in the meanwhile, the amount that has been credited at that time is paid to him, but if he should die the whole amount is paid to his heirs.

"The benefits of a system of this kind are obvious. It serves as an incentive to bring out all there is in a man and also makes him interested to remain with the company. We place great importance on this last point, that of making a man interested in remaining with the company, if he does satisfactory work. The value of a research chemist naturally increases with his accumulated knowledge. It is our policy, therefore, to continue increasing the salaries of our research chemists so that they are high enough to make a position of that nature sufficiently attractive. Too often the policy has been to make the laboratory a stepping stone to other positions to the manifest detriment of the laboratory.

"The general policy of placing a comparatively large amount of responsibility on the men who do the work and having them realize that their efforts are thoroughly appreciated, and will be correspondingly rewarded if results are obtained, has contributed to make the operations of the laboratory a decided success, for it has been calculated that the laboratory has saved the company about 300 per cent of the sum expended thereon in the last three years. This amount, however, does not represent the real saving effected by the laboratory. It is based wholly on the visible direct saving brought about in the operation of a few manufacturing processes, where the saving on materials used, due to increased efficiency, could be directly computed in dollars and cents. The indirect gain due to improvement in product, introduction of new products, etc., has been wholly left out of this calculation. I do not think it unfair to judge of the success of a commercial research laboratory by the pecuniary saving effected thereby. No corporation is going to maintain a laboratory for any considerable length of time if it is run at a dead loss.

"The ultimate criterion of the success of a commercial laboratory is whether it pays or not, and in this it differs from research work carried on for purely scientific purposes. This fact may not always be easy to determine, as the benefits are often indirect."

Dr. Comey concluded by expressing the conviction that while it is useless to expect results from a small laboratory with untrained men, yet it would be a profitable undertaking for every large corporation in this country engaged in industries connected closely with chemical problems to establish research laboratories on a large scale, where investigations connected with their manufacturing operations can be carried on with the assurance of all necessary funds.

The Research Laboratory Working Independently.

Individual Research and Officialized Competition.

Mr. P. McN. Bennie, of the FitzGerald & Bennie Laboratories, Niagara Falls, N. Y., presented a paper on "the research laboratory working independently."

"Research, by its very nature, is a thing dependent, requiring men and means; it presupposes the existence of a place where work may be done, a laboratory.

"It is not necessarily always profitable, as measured by dollars and cents, although its results may be extremely useful. The money expenditure is not, and should not be considered, an investment, for while that which is learned may be potentially valuable, it is not always a quick or convertible asset.

"Therefore, the research laboratory, working independently, eventually produces a lengthening list of discontented clients, because the expenditure which they insist upon considering a sure-thing investment turns out to have been an unprofitable speculation. In that respect the haphazard client of the independent research laboratory is very hard to educate. The ray of sunshine in this is that occasionally it does find a client broad enough and with sufficient experience to appreciate a negative result—for the money it saves.

"With the ordinary analytical laboratory such is not the case. Every completed analysis is a result, disappointing sometimes to the client, but still a result for which the laboratory is not blamed. A physical laboratory may test a piece of steel, for example, and while the specimen may prove to have

undesirable properties, such as low tensile strength or fragility, it is still a result, and no sane man thinks of holding the laboratory responsible for the result.

"Happily all research laboratories do not have, in addition to their other problems, the problem of the disappointed client. Some of the best-known and most appreciated organizations are those that have but one client—themselves. I refer now to laboratories such as are maintained and supported by large companies, like the General Electric Company, the National Carbon Company, Norton Company, Du Pont Powder Company and the General Chemical Company. Magnificently equipped as to men, munificently supplied with means, they have the apparatus and ammunition, so to speak, for effective attack upon the unknown. Such is research. It is gratifying to be able to record that among these, with some of whom we have had the pleasure to co-operate, do we find our most satisfying and satisfied clients.

"For effective research both men and means are essential, but the greater of these is men. The research workers of the future must be drawn from the young men of to-day, and these must receive their training in institutions conducted to that end. The young person should be carefully guarded and guided by those competent to do so. Then, to make the training useful, opportunity must be given to apply the knowledge gained, to exercise in work that which has been acquired in preparation, to obtain experience, and thus to develop the ability to do research.

"In each of these respects, preparation and practice, there are influences tending to restrict the usefulness of the prospective research worker. I believe that some allusion to these matters is pertinent and justified, particularly as to the sociological aspect. It is sad to relate that many colleges and universities exhibit distinct signs of commercialism, openly and even boastfully. I have recently seen reports where great stress was laid upon the large increase in the number of students and faculty, as though numerical strength should be considered an index of the quality of instruction given.

"Only a few days ago a graduate of a prominent university in the East told me that during his several years' attendance he considered himself fortunate if he saw his professor once a month. Upon these rare occasions he was given a few brief minutes, with the intimation that the professor must return to his work. His work, if you please, consisted in carrying on important researches for a company, and for a consideration. Another instance is that of the same person holding a professorship in two widely separated institutions of learning, where it is obviously impossible to give but a portion of his time to each. In this case great pride is taken in the fact that the professor has been able to prevail upon manufacturing concerns to appropriate sums of money for the purpose of commercial research by the professor and students. What the operating staffs of the companies affected think of such intrusions is not mentioned.

"This is all very well for the professors, but how about the students? Are they only a consideration of secondary importance? Commercialism of this sort is already visible in the work and attitude of students, and thus we have the spectacle of what should be a course of preparation at an institution of learning degenerating into a mere apprenticeship in money-making, the university becoming an institution of earning a shop.

"Our student graduates; he enters upon the practice of the profession for which he thinks he has prepared. Let us assume that his course has been in mining and metallurgy. The first work that presents itself, because it is generally the easiest to get, is some assaying. But he finds himself in competition with this or that state-subsidized school of mines, where assays are done at a nominal charge, too low to be profitable to practitioners. If he undertakes research on some problem in mining or metallurgy, he may find himself in competition with this or that government-supported bureau.

"Or let us assume that he has been working upon some specific problem, and is ready to realize a profit, either in money or acquired reputation, from the time and effort thus spent, only to find that a government report has just been issued by Bureau 'X' covering similar work, 'copies 5 cents.'

"Then, there is the Colorado movement, petitioning for federal aid to mining. . . . The people are being educated to demand the creation of this or that bureau to spend the money of all the people for something most of them know nothing about, do not want, and have no use for, for the benefit of the few.

"And so our student finds himself narrowed in training and restricted in opportunity, engaged in an undignified struggle for substance and subsistence with his alma mater on one hand, and officialized competition on the other.

"Destroy individualism and you destroy effective research. Stop research and the progress of science practically comes to a standstill.

"Darwin, Tyndal, Huxley, and Spencer, a quartette of the grandest contemporaneous thinkers the world has known, were the products of individualism and independent thinking, as contradistinguished from the necessarily restricted thinking of a governmental bureau."

In conclusion Mr. Bennie quoted the words of one of them, from Sections 851 and 852 of Spencer's Principles of Sociology: "This general drift towards a form of society in which private activities of every kind, guided by individual wills, are to be replaced by public activities guided by governmental will must inevitably be made more rapid by recent organic changes, which further increase the powers of those who gain by public administrations and decrease the powers of those who lose by them.

"There seems no avoiding the conclusion that these conspiring causes must presently bring about that lapse of self-ownership into ownership by the community, which is partially implied by collectivism and completely by communism.

" . . . . To bring about the change it needs but gradually to extend State-regulation and restrain individual action. If the central administration and the multiplying local administrations go on adding function to function, if year after year more things are done by public agency, and fewer things left to be done by private agency, if the businesses of companies are one after another taken over by the State or the municipality, while the businesses of individuals are progressively trenched upon by official competitors, then, in no long time, the present voluntary industrial organization will have its place entirely usurped by a compulsory industrial organization. Eventually the brain worker will find that there are no places left save in one or other public department, while the hand-worker will find that there are none to employ him save public officials. And so will be established a state in which no man can do what he likes, but every man must do what he is told.

" . . . . An entire loss of freedom will thus be the fate of those who do not deserve the freedom they possess."

The Commercial Aspect of Research

Organization and Accounting of a Research Laboratory.

Dr. CHARLES F. LINDSAY, of the Remington Arms-Union Metallic Cartridge Company, presented a paper on "the commercial aspect of research." He quoted a remark by President Remsen in an address at an alumni dinner of Johns Hopkins University to the effect that the Government, large privately endowed foundations, and the research laboratories of the large manufacturing concerns are hindering the advance of research work in the universities each in its own way, but all acting toward the same end. They all divert some of the best men from the scientific life of the universities.

But in so far as a university has succeeded in instilling the investigator habit into its students and staff, in just such

measure is it fulfilling its highest object and ideal, and if it be a generality that at the present time commercial research has robbed our colleges and universities of some of the best men, the compliment is to the university and its methods.

The main object of Dr. Lindsay's address was the economic and business-like management of a research laboratory. It is a general principle that there are no results of laboratory experience which are not in their due order absorbed into the province of technology and, of course, once in technology, if not before, they must be thought of commercially. A difference between older manufacturing and operating methods and those of the present day is in the haphazard way such facts became formerly of technical importance, while to-day this is not left to chance, but is brought into use through the research laboratory.

The only difference, then, between purely scientific research and commercial research is one of degree and not of method or quality. The commercial chemist feels the time element more strongly. Commercial interests must of necessity take the place of scientific interest as defining and devoteing the subject to be studied and worked on.

Every research laboratory engaging in commercial work, no matter for what reason it was founded, must be of service or fail on a business basis. Every such laboratory must pay or be a failure. "By paying I do not mean that each year must show a cash balance sheet in favor of the laboratory, but it must show such a balance when account is taken of the work done and service rendered for which perhaps the books of the company may show no adequate return. In other words, it must be regarded as paying in the eyes of owner or directors."

The amount of money and time to be spent in an investigation is a problem which comes before a laboratory director very frequently, and the proper decision of which is of the utmost importance to him and his work.

In a large manufacturing concern each and every department has its own special problems which are brought to the research laboratory by their head, each man dilating on the importance of his requirements. It is usually utterly impossible to tackle all of them at once or perhaps more than one at a time. Here comes often the necessity for a careful investigation by the head of the laboratory of the individual needs and the making of a just choice independent of interest of the problem for active work. It may be, and often is, the case that the direct responsibility of such choice is taken off the shoulders of the head of the laboratory, but it is also true that in a great majority of cases his recommendations are acted on and the real responsibility is his.

"At this time also must be formed an idea which usually can only be an educated guess, though in some cases can be accurately calculated—of the commercial importance of the investigations. If the work be a success, are the returns to be large or small? What will be the saving in factory practice if the change suggested can be worked out?" . .

"How shall the work be done to do it most economically? And I use 'economically' here in not the sense of cheapest, but as applied to the whole problem of time, money, and ultimate gain to your firm. Will it pay to put all available force at work and endeavor to attack the problem in a variety of ways and get it over with or is it best to take your time, go slow, put a very small force, perhaps only one man and maybe only part of his time and let the work gradually develop. These are perhaps the two extremes. Each case must be considered separately as each new work comes along, but I believe no new study should be undertaken without just such preliminary deliberation.

"There are, of course, investigations so broad in their scope and of so far-reaching a consequence and of so great an importance to your firm that the actual amount of time and money to be spent may become not a question of how much to spend, but what is the most that can be put into the work judiciously. It is on such a point as this that experience is really the only guide. Take the case of the development and improvement in lighting by electrically heated incandescent filaments. I do not think that the question ever entered Dr. Whitney's mind or the thoughts of the officials of the General Electric Company as to how far they would go in such a study, but how most judiciously they should spend time and money. New methods of study had to be worked out, familiarity obtained with little-studied elements, and a tremendous amount of work had to be done before it was really known how best to attack such problems. This work necessarily had to be slow, because the way was unprepared, but as these preliminary problems were worked out, it became good policy to put more and more men on the work and money was sunk right and left in a tremendous piece of experimental investigation, of which the present tungsten or 'mazda' lamp of the General Electric Company is the result.

"There are manufacturing concerns in this country which are so large and whose products are so varied that as far as materials and the necessary apparatus for experimental or development work are concerned are almost self-contained." This is, for instance, the case at the works of the General Electric Company.

"But the larger number of us, I believe, find a real problem in determining at times what to do when you require apparatus, machinery or conveniences that your plant does not offer. Under such conditions you may often find that to do the work properly will require an expenditure of time and money beyond what might be called the probable value of the experiment. On the other hand, there is no doubt that in general such experiments as the above condition brings to your mind, can be performed cheaper outside, for instance, by a manufacturer of such machinery as you desire or by some one who has in use such machinery or apparatus. At times you are really between the horns of a dilemma. On one side there is the natural desire for secrecy until such experiments be carried to completion and, second, the wish to overcome an unnaturally high expense in its performance. I take it as a high compliment to the American manufacturer that you can usually bring such experiment to him and have it performed with accuracy and dispatch and with a consideration of the confidence placed in him."

Dr. Lindsay thought that a good deal of mutual help might be extended between different research laboratories in the loan of certain apparatus or that there might be a field for the Bureau of Industrial Research under Government control.

"Not only do I feel that accurate commercial accounting is necessary in a modern research laboratory covering the expenditures over a given period for salaries, labor, materials, etc., but that as far as possible, or as the importance of the subject demands, an accurate and detailed accounting of each and every separate price of experimental work should be kept. For in *no* other way that I know of is it possible to accurately proportion laboratory charges among the various departments of the plant or to assign any accurate development charge to a new article or process.

"Of course, I realize that the carrying of this process to the limit is, in general, unnecessary and involving useless expense and that it is usually quite sufficient to keep the charge on miscellaneous and small investigations collectively and that only segregation of charges need be made on the more important and expensive work.

"As explained before, an estimate of the commercial importance of a proposed investigation should be made before its start and at the same time an idea obtained of the extent and expensiveness of the investigation. On this data application should be made for an appropriation covering the cost of the proposed study. With this appropriation, which may be called plant order, manufacturing order, experimental order or plain appropriation, duly numbered, it is perfectly possible and easy in any well-accounted plant, by carefully charging all time and material against such number, not only to accurately

keep the total cost of the work, but the progress of it can be followed as closely as required. . . .

"In other words, let a piece of experimental work as far as the accounting is concerned follow the same routine that is generally followed in erecting a new building, buying new machinery, or in putting a production order through the plant."

As to size of staff, Dr. Lindsay suggested that, as a rule, the staff should not be increased on account of pressure on one particular piece of work alone, but only when the increased force is permanently necessary and justified. "The only exception to such a working policy is, in my opinion, during the period of the summer vacation when it may be good policy, not so much with an idea of any present help, but to keep in touch with and find out good men, to temporarily engage help at a nominal salary from among the summer workers."

Roentgen Ray Research.

The Use of Tungsten for the Target.

Dr. W. D. Coolidge, of the Research Laboratory of the General Electric Company, said that most phenomena which are now known about Roentgen rays were already described by Roentgen. But since his discovery, wonderful strides have been made in creating and extending their field of usefulness, though a great deal of fascinating work remains still to be done.

Dr. Coolidge then demonstrated concisely the essential features of a Roentgen ray tube. What is being done in a Roentgen ray tube is to first produce a stream of rapidly moving electric charges and then to bring them to rest with abrupt suddenness by the "target." This produces the Roentgen rays.

To produce a stream of rapidly moving electric charges, a vacuum is required. The cathode, which must not disintegrate, is invariably made of aluminium. Aluminium is very good for this purpose. The spherical shape is essential to direct the electrons in a stream to the target.

In the target we have a remarkable case of highest concentration of energy. Since the percentage efficiency of transforming the kinetic energy of the moving electric charges into Roentgen rays is always very low, most of this kinetic energy is transformed into heat. It is for this reason that the material of which the target is made should have as high a melting point and as low a vapor pressure as possible. Heretofore platinum has been generally used.

But now since tungsten has become a commercial metal through the development of the tungsten lamp, the advantages of tungsten over platinum for target construction have been recognized. These advantages are that tungsten has a higher melting point than platinum, has a lower vapor pressure at high temperature, and also has a better heat conductivity which permits the carrying off of the heat produced in the target. Finally the density of tungsten is sufficiently high to bring the electrons suddenly to rest. For all these reasons tungsten is now finding very much favor as material for target construction.

Dr. Coolidge then discussed in detail different methods of taking care of the heat produced in the target, and finally referred briefly to the utilization of Roentgen rays for practical purposes. Some excellent radiographs were shown. As the interpretation of radiographs is difficult, it is generally left to specialists. Stereoscopic pictures are now often used. Chemical stunts have also been performed with the aid of Roentgen rays.

Dr. Coolidge's paper was illustrated by a number of very interesting exhibits.

The discussion of the papers was opened by a few words of Dr. Edward Weston, the distinguished electrical and electrochemical pioneer.

Dr. L. H. Baekeland spoke at greater length on a certain phase of the tragedy of chemical research, the balance has made chemistry possible, but until we get rid of the balance, chemistry will remain stagnant. He then spoke of the life of Pasteur and his wonderfully successful research work done under absurd external conditions. As to the work done by our Government bureaus, Dr. Baekeland referred to a visit to the Bureau of Standards, the Bureau of Chemistry and other bureaus in Washington as an inspiration, as it showed underpaid scientists doing faithfully splendid work.

The meeting, which was exceedingly well attended, then adjourned.

Resuscitation From Electric Shock.

The first meeting of the Commission on Resuscitation from Electric Shock was held in the board room of the National Electric Light Association, New York, on Feb. 22. This commission was organized upon the initiative of the National Electric Light Association, and has for a purpose the study of electric shock and the preparation of a set of rules for first aid in case of electrical accident. The commission is composed of members of the American Medical Association, National Electric Light Association, and American Institute of Electrical Engineers, as follows:

Nominated by the American Medical Association: Dr. W. B. Cannon, professor of physiology, Harvard University, chairman; Dr. George W. Crile, professor of surgery, Western Reserve University; Dr. Yandell Henderson, professor of physiology, Yale University; Dr. S. J. Meltzer, Rockefeller Institute for Medical Research, New York; Mr. W. D. Weaver, editor *Electrical World*, secretary. *Nominated by National Electric Light Association:* Dr. E. A. Spitzka, professor of general anatomy, Jefferson Medical College; Mr. W. C. L. Eglin, electrical engineer Philadelphia Electric Company. *Nominated by American Institute of Electrical Engineers:* Dr. Elihu Thomson, electrician, General Electric Company; Dr. A. E. Kennelly, professor of electrical engineering, Harvard University.

At the meeting in New York City the medical members of the commission unanimously adocated the Schaefer, or prone, method as the best means in the hands of laymen for maintaining respiration in victims of electric shock, and the commission formally voted to recommend this method. (The Sylvester method, in which the patient is placed on his back, has heretofore been used principally in similar charts.) A chart is now being prepared which will give details of first aid in cases of electric accidents and will describe fully the method of applying artificial respiration.

The Sherardizing plant of the Ohio Brass Company, Mansfield, O., is described in that company's *O-B Bulletin*. The process consists in coating iron castings with zinc by placing the castings in drums with a quantity of zinc dust, sealing the drums and running them into furnaces, where they are rotated and heated at a suitable temperature. As is well known, the zinc dust will not melt at temperatures above the melting point of zinc, owing to a film of zinc compound which surrounds each particle of zinc. In touching the iron, however, this film seems to be broken and the zinc is deposited on the casting, forming a coating which is said to be superior to that formed in the ordinary process of galvanizing. When the castings have been heated for a sufficient length of time they are drawn from the drums, after cooling, and a selected number of pieces are tested by immersion in a solution of copper sulphate. The chemical action dissolves the zinc and precipitates copper. Ultimately the zinc will be totally dissolved at points, and the iron will be exposed. The standard test adopted is that the casting shall withstand four successive immersions of one minute each without having the iron show through the coating of zinc. Between each immersion the casting is brushed and washed in clear water.

The Granby Smelter.

BY GEORGE M. LEE.

The Granby Smelter, the largest copper smelter in the British Empire, is located on the north fork of the Kettle River, one mile from the city of Grand Forks, British Columbia. It is owned and operated by the Granby Consolidated Mining, Smelting & Power Company, Ltd. The present company is the outgrowth of the organization and consolidation of smaller companies, starting in 1901 with the combination of the Old Ironsides and the Knob Hill claims at Phoenix, B. C. The credit of organizing and financing is due to Mr. J. P. Graves, of Spokane, who is the vice-president and general manager of the company. Mr. George Martin Luther, of Boston, is the president.

The company now owns forty-three claims and fractions in the district surrounding Phoenix, comprising, in all, some 1050 acres, and the smelter site of 118 acres at Grand Forks.

FIG. 1.—GENERAL VIEW OF SMELTER, SHOWING CONVERTER BUILDING, BLAST FURNACE BUILDING, SAMPLE MILLS, WITH BLOWER ROOM AND SHOPS IN FOREGROUND.

Below is a statement of the financial operations of the company from 1904 to 1911:

* Excluding marketing Blister Copper.

The ore is a low-grade copper ore with some value in gold and silver and is of the following average analysis:

	Per cent.
SiO_2	35
Fe	13
CaO	17
MgO	3
Al_2O_3	8

The iron is present as silicate, uncombined oxide and sulphide. The lime and magnesia are present as carbonates.

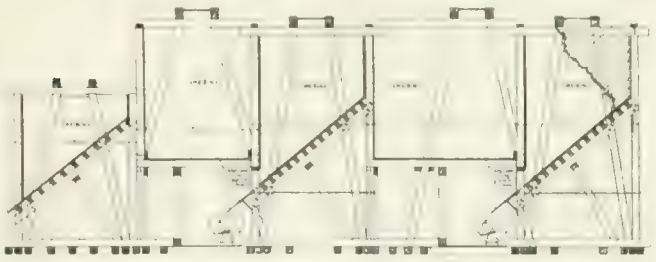

FIG. 2.—NEW ORE AND COKE BINS.

Chalcopyrite is the only copper-bearing mineral and the gold and silver value is carried in it. The ore is self-fluxing, which is a fact worthy of note, as otherwise the cost of smelting would advance materially. Since the organization of the company 7,299,911 tons of ore have been treated by the smelter and at present there are about 6,500,000 tons of ore blocked out in the mine. During the last year, moreover, the company developed more ore than was mined.

The company commenced the building of the smelter with the idea of adding units from time to time as the output of the mines was increased, and they have pursued that policy up to the present time, and as the smelter stands today, it shows a marked metallurgical and mechanical efficiency.

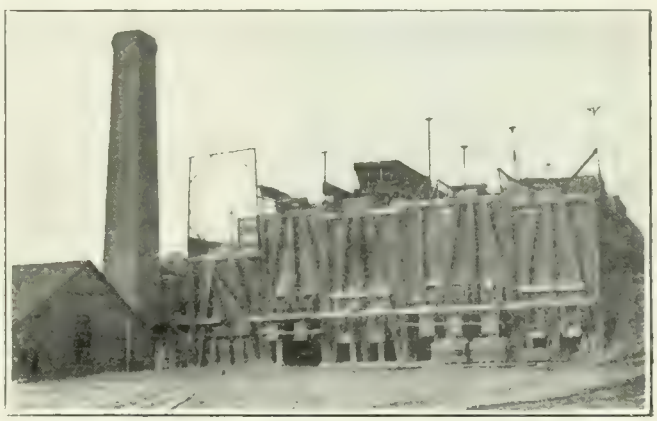

FIG. 3.—END OF BUNKERS.

Receiving and Storing Ores.

When the original bunkers were planned the Canadian Pacific Railway afforded the only means of transportation between the mines and the smelter, and the capacity of the bunkers at that time was limited to 1000 tons. In 1906 the Great

Northern Railway Company extended its system to both mines and smelter, and the capacity of the receiving bunkers was then increased to 9000 tons for ore and 7000 tons for coke.

The ore bunkers are built in three sections, each section being 17 ft. wide and 770 ft. long. The bottoms are inclined at 45° and the lowest point is about 10 ft. from the ground. Partitions divide the bunkers into 14-ft. bins, so that the ore from the different stopes and drifts can be kept separately.

The coke bunkers are placed between the ore bunkers, as shown in Fig. 2. They are 20 ft. and 17 ft. wide, respectively, and are the same length as the ore bunkers. They have flat bottoms to increase the capacity and are not divided into bins. Both coke and ore bunkers are of heavy wooden construction. Underneath and running the length of the bunkers are three tracks for the charge cars. Two of these tracks are placed so that ore and coke can be charged into the same train. The third track serves one outside row of bins.

Sampling Mills.

There are two sampling mills, identical in construction, but differing slightly in their method of operation. One of these is used exclusively for custom ores and the other for Granby ores and converter slag. The first treatment in both mills is similar and is as follows: The ore is trammed in push cars from the bins to a gyratory crusher. The product from the gyratory, which will pass through a 3-in. ring, is elevated to the top of the mill and the first cut is taken. In the Granby mill this amounts to 20 per cent of the sample and in the custom mill it varies from 10 per cent up, according to the size of the shipment. In the Granby mill the reject passes to a storage bin, while the sample is reduced to ½ in. in a Blake crusher and another cut of 20 per cent is taken, the reject going to a storage bin as before. The sample then passes rolls set at ¼ in. and a third cut of 20 per cent is taken. This is quartered by hand and a sample of about 20 lb. is taken to the assay laboratory. For each sample four half-cars are taken at random each week from each of the three crushers at the mine. This gives three 70-ton samples, which amount is less than 1 per cent of the ore mined.

In the custom mill the first cut is saved in a storage bin, while the reject passes completely through the mill with the samplers idle. The reason for this procedure is that custom ores, which are mainly quartz ores, require crushing before they are used in the converters, and the sampling mill becomes, temporarily, a reduction mill. The sample is then put through the mill and a 20 per cent cut is taken after each reduction in size. The final sample from the rolls is split on a riffle, quartered by hand and sent to the laboratory. The capacity of each mill is 40 tons per hour and the storage capacity for crushed ores is about 5000 tons. Snyder samplers are used in both mills.

Blast Furnace Department.

The first unit of the blast furnace department, which was built during 1899 and 1900, consisted of two furnaces 44 by 180 ft. at the tuyeres and

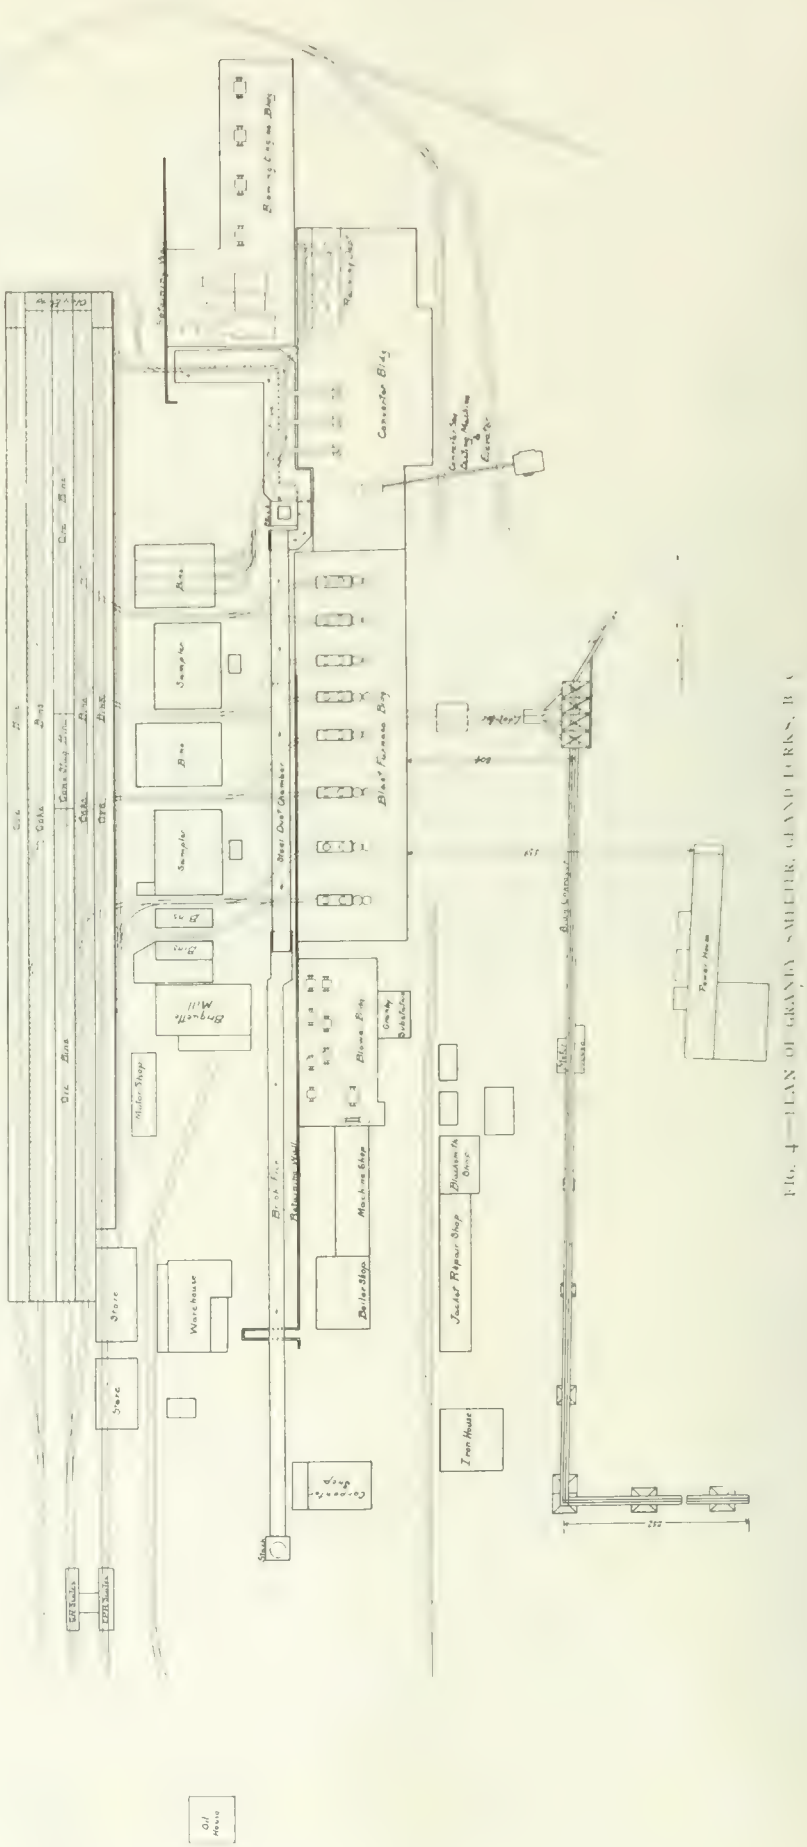

FIG. 4.—PLAN OF GRANBY SMELTER, GRAND FORKS, B. C.

having 5-in. tuyeres spaced 17¾ in. center to center. These made a 50 per cent matte, which was shipped to New York for refining. The slag was granulated and handled in launders.

Two years later two furnaces of the same design and size as the first were completed and put in operation, together with a converting plant of three small converters. In 1904 two more furnaces were added and a system of mechanical

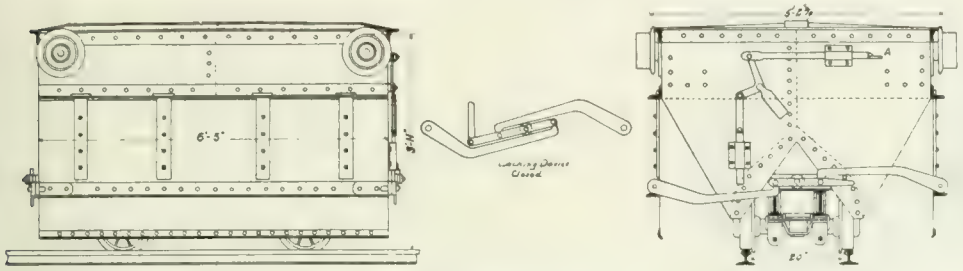

FIG. 5.—CHARGE CAR.

end charging was substituted for the system of side charging by hand which was in use up to that time. At this time two furnaces of a different design were planned to meet the requirements of an ore of higher sulphur content. In these the length of the furnaces was increased to 213 in. and the width at the tuyeres to 48 in. The tuyeres were 3½ in. in diameter and were spaced 8 11-16 in. from center to center. The lower jackets were straight line jackets.

In 1908 experiments under the direction of Mr. W. A. Williams, smelter superintendent, were made the basis for still further changes in design. All the furnaces were lengthened to 266½ in. and the column was deepened from 11 ft. 9½ in. to 15 ft. 8 in. Since then no further changes have been made.

The eight furnaces are housed in a steel building 290 ft. long and 71 ft. wide. They are in a row with their long axes at right angles to the length of the building and are spaced 27 and 41 ft. apart, as shown in the plan (Fig. 1).

The foundations are of concrete and the hearths are 2 ft. 4 in. above the level of the tapping floor. The jackets are of riveted steel, 7-16 in. thick on the inside and ⅜ in. thick on the outside. They extend from the hearth to the charge floor in two sections as shown. The lower jackets are 7½ ft. long, with a 4⅞-in. water space, while the upper are 7¾ ft. long and have a 3 5-16-in. water space. Water enters the upper jacket near the bottom and is deflected toward the bottom. It is drawn off at the top of the jacket and then circulates through the lower jacket in the same manner. This arrangement keeps the upper jackets cool and does not chill the tuyeres too much. The temperature of the water as it leaves the lower jacket is about 140° Fah. The eight furnaces require 2000 gallons per minute, or an equivalent of 3 gallons per minute per square foot of hearth area.

Air is delivered to the furnace through a 24-in. bustle-pipe connected with either one of two mains. The supply mains are 6 ft. in diameter and run lengthwise of the blast building behind the furnaces. Each furnace requires about 25,000 cu. ft. of air per minute and the blast pressure is from 24 to 28 ounces.

Above the charging floor the tops of the furnaces are built of red brick and have a fire brick lining. All brick work is reinforced and bound with stays and fifty 6-lb. rails. An opening is left in one end of the furnace for the entrance of the charge train and two hand holes are left in one side to allow for the tripping of the cars. No gate or curtain is used over the charging aperture.

The system of end charging was devised in 1904 by the then local manager, Mr. A. B. W. Hodges, and is worthy of comment for its efficiency, as well as for its uniqueness.

As shown by the sketch, in addition to the regular trucks, the charge cars have a wheel at each of the upper corners. When the car enters the furnace these wheels engage rails embedded in the side walls of the stack. At the same instant the lower trucks leave the ordinary rails which are discontinued at the entrance to the furnace, and the car is then suspended in the furnace. The gates of the cars are tripped by means of a rod inserted through the hand hole which engages the arm marked "A." The weight of the charge swings the gates and the charge is delivered toward the outside walls of the furnace. There is a slight tendency for the coarser particles to concentrate in the center and along the outside, with the fine in the intermediate positions. This distribution gives an even descent of the charge. The time required from the instant the first car enters the furnace until it is withdrawn is, in actual practice, from 10 to 15 seconds.

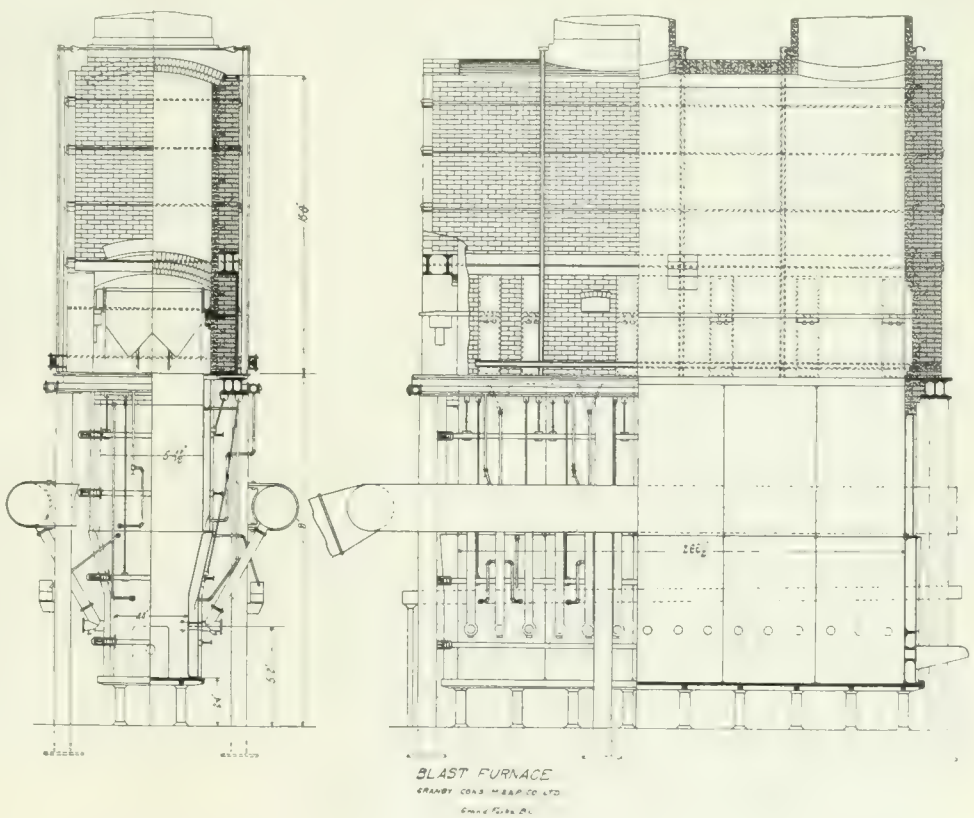

FIG. 6.—BLAST FURNACE DESIGN.

Three cars making up the charging train hold about 10 tons of ore and are handled by 30-hp electric locomotives. Coke

and ore are charged separately and complete charges of both are made every 20 to 30 minutes. The charging cars are divided into four sections, and in case of uneven descent of the charge in the furnace ore can be distributed to the required places by omitting the charge from certain sections of the car.

The average daily capacity of each furnace is from 500 to

FIG. 7.—BLAST FURNACES, FROM TAPPING FLOOR, SHOWING SETTLERS.

600 tons of ore. A maximum for eight furnaces of 5000 tons has been reached, equal to 7¾ tons per square foot of hearth area in 24 hours. The coke amounts to about 12½ per cent of the ore charged. During the year ending June 30, 1910, the blast department smeltered the following tonnage:

	Tons.
Granby ore	1,175,548
Foreign ore	8,076
Flue dust	8,406
Converter slag and matte	52,678

The matte and slag discharge continuously from one end of the hearth into the first of a series of two settlers. The

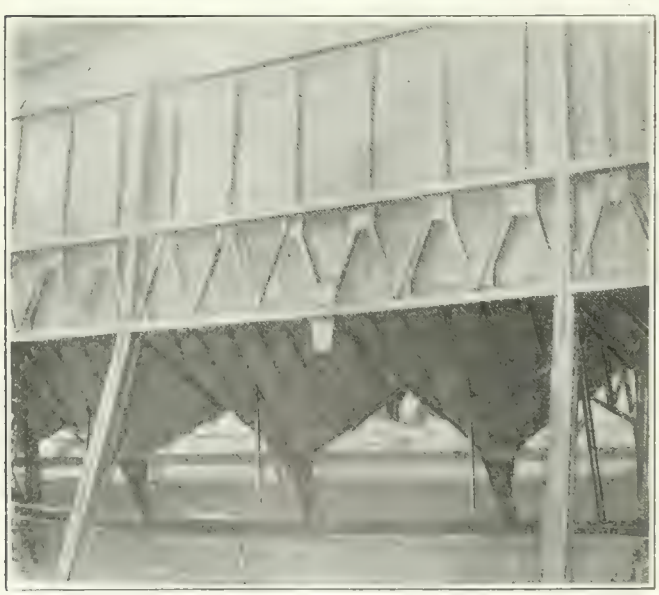

FIG. 8.—DISCHARGE HOPPERS ON BOTTOM OF STEEL DUST CHAMBERS.

first settler is 5 by 7 by 3 ft. deep and is water jacketed. It consists, primarily, of a ⅜-in. steel shell resting on a removable cast iron bed plate 2 in. thick. A course of fire brick is laid over the bottom and around the sides. The second settler is of the same general construction as the first, but is smaller, being 4½ by 5 by 3 ft. deep.

The first settler makes a practically complete separation. It is tapped as often as is necessary and the matte transferred to the converter building by a 10-ton electric crane. Any matte caught in the second settler is tapped once a day, cooled, broken and returned to the furnaces. Settlers are changed by means of the crane and the change requires 30 minutes.

Slag flows from the second settler into 5-ton slag pots mounted on trucks. These are handled, six or nine at a time, by 12-ton steam locomotives. These pots are dumped by hand, as they are in unstable equilibrium when full, and all that is required to dump them is the releasing of a catch. The slag analyzes approximately as follows:

	Per cent.
SiO_2	44.8
FeO	19.0
CaO	21.8
Al_2O_3	10.2
MgO	3.9
Cu	0.15 to 0.20
Au	Trace
Ag	Trace

All gases and flue dust are drawn from the furnaces into a chamber in which the greater part of the flue dust is col-

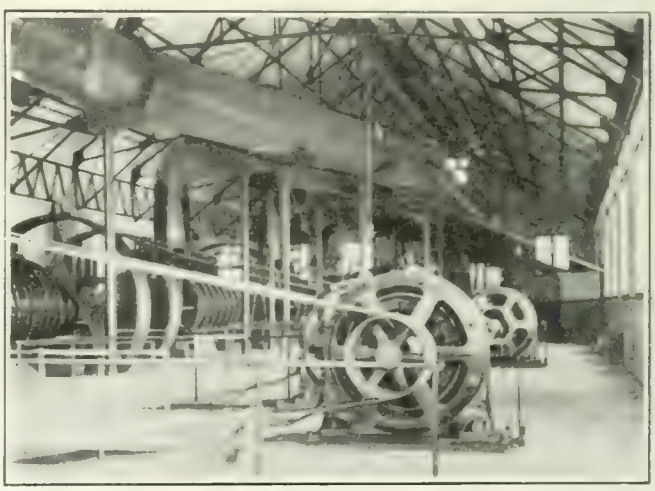

FIG. 9.—INTERIOR OF BLOWING ENGINE ROOM.

lected. This is a rectangular steel chamber 15 by 13 ft. in section and raised 21 ft. above the feed floor. It is parallel to the blast furnace house and at one end connects with a brick flue leading to a circular stack 13 ft. in diameter and 150 ft. high. The other end connects with a similar brick flue leading to a stack 12 ft. square and 153 ft. high. Flue dust caught in the steel chamber discharges from the hoppers on the bottom into a drag conveyor. This carries the dust to the briquetting mill, where it is moistened and briquetted in a White briquetting machine which has a capacity of 50 tons a day. All flue dust from the brick flues is cleaned up with shovels and wheeled to the mill in larrys. The briquetts are not dried before they are charged into the furnace.

Converter Plant.

When the smelter was first put in operation matte was shipped to New York for converting, but almost immediately the need for converting at the plant was recognized, and in 1902 the first converter building was erected. The equipment included three 72 by 100-in. stands and shells and the necessary copper molds and lining machinery. These converter stands were hydraulically operated.

As the number of blast furnaces was increased the converter equipment became inadequate and in 1909 these stands

were taken out and replaced by three 84 by 120-in. electrically controlled stands manufactured by the Power & Mining Machinery Company. Three 25 hp 220 volt direct current motors furnish the power to operate these stands.

The quantity of matte charged varies from 3 to 9 tons, depending on the condition of the lining. The lining lasts usually for three charges, after which it must be renewed.

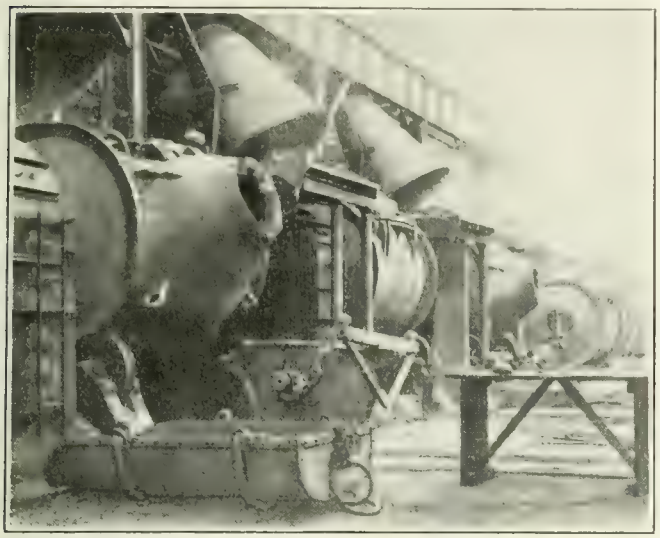

FIG. 10.—THE CONVERTERS, SKIMMING, BLOWING, POURING.

The full capacity of the department is 40,000,000 lb. of copper per year, but for the year ending June 30, 1910, the converters handled 31,868 tons of 37.5 per cent matte and produced 22,754,899 lb. of copper which averaged 98.5 per cent pure. The reason for the difference between the capacity of the plant and the real production is that the converters can handle in two shifts all the matte that the blast furnaces can produce in three shifts.

The copper is cast into 200-lb. bars and shipped to New York for refining. The molds are 24 by 33 in. in section and are mounted on 16-ft. trucks which run directly under the

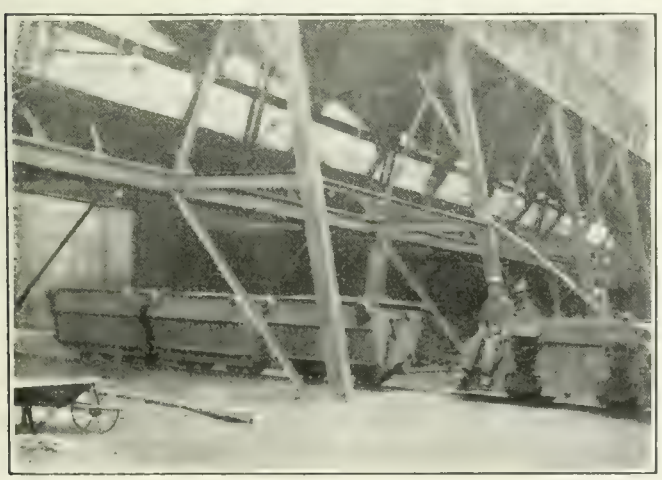

FIG. 11.—CHARGE TRAIN AND PORTION OF STEEL DUST CHAMBER.

converters. These trucks are manipulated by cables and an electrically operated drum.

The slag from the converters, amounting to 100 tons a day, is cast in moulds, cooled, broken and dumped into cars to be returned to the blast furnaces. No mechanical means is used to break the slag, as the fall from the top of the conveyor to the car is sufficient to shatter the pigs. The analysis of the slag approximates 40 per cent silica, 55 per cent iron oxide and from 1 to 1½ per cent copper. The high percentage of iron oxide in the slag makes it valuable to add to a furnace which is running on a highly siliceous slag and also to furnaces that are working badly.

The converters are lined in the usual way with a course of magnesite or chrome brick next to the shell and then a 2-ft. layer of siliceous ore bound with clay. For the year ending June 30, 1910, 13,753 tons of siliceous ore and 4438 tons of clay were used in relining 1,573.5 converters. Fifteen hundred tons of coke were used in drying the converters.

The company has no difficulty in obtaining custom ores of high silica content, with little or no sulphur, iron or lime and containing sufficient value in gold, silver and copper to make them profitable. These ores come mainly from Republic, Wash. The clay comes from Hendrix Cut, Wash. The equipment of the relining department includes clay stalls, quartz bins and three mud mills. The whole department is served by a 40-ton electric crane with a 40-ft. span. A steel building 100 by 240 ft. in size houses the converter department.

Power Department.

Originally the company developed its own power from a power site on the north fork of the Kettle River, about 1 mile from the smelter. For this purpose a dam 25 ft. high, a flume and a powerhouse were erected and the machinery for developing 900 hp installed. At the end of the year 1902, when the plant was enlarged, this installation had become too small and instead of enlarging the power plant the company contracted

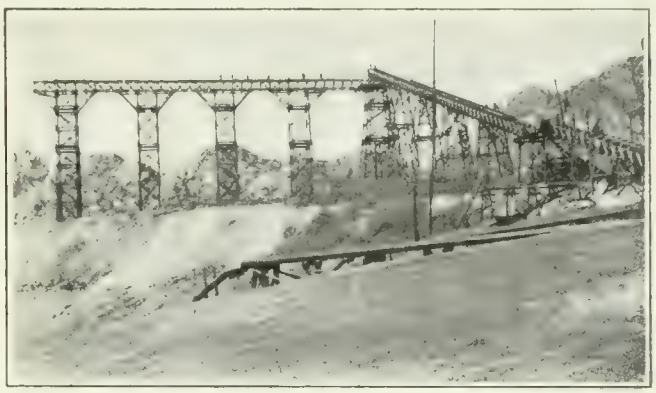

FIG. 12.—SLAG CONVEYOR DURING COURSE OF CONSTRUCTION.

for power from the Cascade Power Company operating on the Kettle River 10 miles below the smelter. In 1906 more power was required and 1200 hp was contracted for from the West Kootenai Power & Light Company. This power is transmitted 65 miles from Boonington Falls at 60,000 volts and is transformed at the smelter to 440 volts before use in the motors.

The Granby power house furnishes 110-volt direct-current for lighting and some 440-volt alternating current for use on the works. The generators are Westinghouse machines, direct-connected to water turbines. The power house also contains six pumps, each capable of delivering 500 gallons per minute against a 200-ft. head. Two of these are driven by water turbines and the other four are motor-driven. At the present time the company has just finished the installation of two more motor-driven pumps with a capacity of 1000 gallons per minute to furnish water for the new slag-granulation scheme.

The blower building has been recently remodeled, the old wooden structure being replaced with one of brick and steel. It contains three No. 7 and four No. 8 Connelsville blowers with capacities of 13,500 cubic feet of air per minute each. There is also one No. 10 blower capable of delivering 30,000 cubic feet per minute. The small blowers are separately driven by 100-hp, three-phase, 400-volt, 60-cycle, Westinghouse induction motors. The large blower is driven by two 150-hp motors

of similar design. There is also a small single stage compressor for furnishing air to the machine shop, at 90 lb. pressure.

The blowing engine room is also of brick and steel construction and contains four No. 10 blowers and three blowing

FIG. 13.—SLAG CONVEYOR DURING COURSE OF CONSTRUCTION.

engines. These are a Nordberg, with 36 by 36 in. cylinders delivering 3700 cubic feet per minute an Allis-Chalmers duplex, 34 by 34 by 36 in., delivering 6000 cubic feet per minute, and a Nordberg, 40 by 40 by 42 in., delivering 10,000 cubic feet. The first two are belt driven by motors of 200 hp and 300 hp respectively. The last is rope driven by a 500 hp motor. These engines supply air to the converters at a pressure of 12 lb. This building also contains a compressor for delivering air at 80 lb. pressure to the relining department, and a 200-hp motor-generator set for furnishing 250-volt current to the electric locomotives and the cranes.

There are also the machine shops, boiler shop, blacksmith shop and carpenter shop, each fully equipped for making almost any repairs. The smelter has just blown in after a four month's shut-down due to the strike of the coal miners in the Crow's Nest Pass and the consequent lack of coke; but as soon as the coke supply is adequate the smelter is prepared to run at the maximum capacity, as everything is in good repair.

Slag Disposal System.

Lack of dumping room within reasonable distance has made a change in the slag disposal system necessary, and the company has just finished the installation of a new system. Orig-

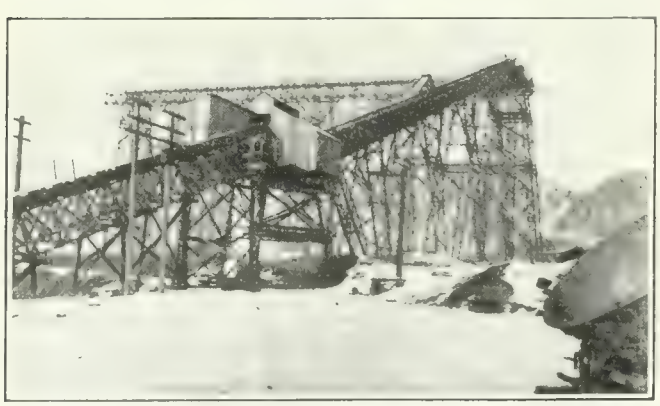

FIG. 14.—SLAG CONVEYOR COMPLETED.

inally the slag was granulated and disposed of in launders, but in a short time the available ground was filled to the highest level possible. So in 1903 the company installed a system of dumping molten slag from pots which were handled by steam locomotives. This system proved satisfactory and economical up until the last year, when the long haul made it expensive and slow. Now the company has gone back to the granulation scheme and plans to elevate the slag and deposit it on the top of the present dump, where there is room for some 5,000,000 tons.

The slag is granulated at the settler by an inclined jet of water from a ½ by 1¼ in. nozzle and falls into an inclined receiving trough of concrete. These troughs are about seven feet long and one foot wide, and connect with wooden launders which carry the slag to the receiving bin. The launders are lined with cast iron plates one inch thick and have a slope of ⅞ in. to the foot. The receiving bins are built of wood and have a capacity of 50 tons of dry slag, or a total of 200 tons for the four bins. From these bins the slag feeds on to a 24-inch belt and is elevated on a 18° incline, a vertical distance of 170 feet to a point 115 feet above the level of the present dump. It then discharges onto a horizontal belt running at right angles to the inclined belt. This belt is 252 feet long and an automatic tripper distributes the slag the length of the belt. When the dump reaches the level of the horizontal belt it will be moved laterally and the inclined belt extended.

The photographs accompanying this article will perhaps give a clearer idea of the smelter than the writer can convey in words.

Grand Forks, B. C.

Effect of Electric Current on Cyanide Solutions and a Simple Way for Their Preparation.*

By Dr. M. G. Weber.

As cyanide solutions give usually a brighter and denser deposit than acid baths and can be employed in almost every case, whereas acid solutions have but a limited field, they are in use in nearly every plating shop.

When one passes an electric current through solutions containing a double cyanide, for instance, double cyanide of copper and sodium, $CuNa(CN)_2$—I mention sodium and not potassium, as sodium cyanide is cheaper and more efficient than the potassium salt—this salt is separated into two parts, the cation Na and the anion $Cu(CN)_2$. If the current density is not too high and the copper salt is present in suitable concentration (about four ounces of metal per gallon) the cation will act with a reducing effect on the double cyanide of copper and sodium and turn out the copper on the cathode, according to the following equation:

$$CuCN\ NaCN + Na = Cu + 2NaCN.$$

We do not see, then any hydrogen gas developed, but free cyanide of sodium is formed. On the anode an oxidation takes place, the primary anion $Cu(CN)_2$ combines with the anode copper to the single cyanide:

$$Cu(CN)_2 + Cu = 2CuCN.$$

Cuprous cyanide is only soluble in cyanide solution, and the anode becomes covered with a dirty green mud offering quite a resistance to the current, unless free cyanide is present. We understand, therefore, that the cyanide being formed at the cathode is absolutely necessary to keep the bath in the proper working condition. In order to bring the free cyanide from the cathode quickly together with cuprous cyanide on the anode it is of advantage to stir the solution and also to heat it up, as in this way the diffusion will be considerably increased.

In case the current density on the cathode is too high, which can be perceived from an intense bubbling up of gas, the sodium no longer acts with a reducing effect, but is discharged and forms with the water of the bath sodium hydrate and hydrogen. The free cyanide is, therefore, lost, and this is the reason why cuprous cyanide on the anode cannot be entirely dissolved; a sludge will remain, dropping to the bottom of the tank.

* A paper presented before the Electroplaters' Association on February 10, 1912.

In order to bring this mud in solution, as is necessary to prevent the electrolyte from becoming impoverished in metal, sodium cyanide should be added. By using too high a current density on the anode molecular cupric cyanide is set free, which combines with water to basic cupric cyanide, forming a green mud. The reaction is as follows:

$$Cu(CN)_2 + H_2O = Cu{<}\begin{matrix}OH\\CN\end{matrix} + HCN.$$

This hydrocyanic acid becomes polymerised and forms an insulating, cocoa-colored film which adheres to the anode. The addition of cyanide will bring this compound into solution.

In order to facilitate the dissolving of the anode metal and the secondary deposition at the cathode we add so-called conducting salts to the bath. If sodium sulphate, for instance, is used, the cation (Na) decomposes the copper sodium cyanide, copper being deposited, and simultaneously sodium cyanide is formed. The anion, e. g., SO_4, acts on the double cyanide in a known manner and cupric cyanide will result, which dissolves the anode metal.

It is interesting to note the conditions of voltage and current density which are required for cyanide solutions; for example, we take copper cyanide solution again. The ordinary voltage for a solution of this kind in a cold stage ranges between three and five volts. If, however, we use a hot bath, say from 170° to 180° F., in connection with a moderate current density and agitate it well we need no more than one volt. The current density for cold solution is about 3 to 4 amp. per square foot, whereas using hot, well stirred electrolyte we are able to go up to 20 to 30 amp. and still obtain a first-class deposit.

The preparation of cyanide baths according to older recipes, as, for example, that of Roseleur, is rather complicated. The chemicals must be pure and must be mixed carefully, in definite proportions and in a certain order of succession. It is difficult to be sure of the purity of the chemicals, and we all know how easy it is to make mistakes in weighing and mixing. Furthermore, one has to bear in mind that much time is lost in making the solution ready for use, especially for gold and silver plating, where most people start with the metal. The fumes given off in the preparation of solutions are disagreeable and dangerous.

All these difficulties and troubles are obviated by the use of some new products which are sold under the name "trisalytes." They combine in one salt all the necessary ingredients for plating baths; that is, an alkali cyanide, a cyanide of the metal to be deposited, and a conducting salt. The metal contents of these trisalytes are always constant, and in order to make up a plating bath it is only necessary to dissolve one of them in water. Voltage, current density and all other conditions remain just the same as in baths prepared after the old method.

By making baths with trisalytes fumes and poisonous gases are avoided, also there is absolutely no chlorine present, which has such a destructive corrosive action on the hooks on which the anode plates are fastened.

The trisalytes baths have a further advantage: that is, a longer life. They contain only the necessary ingredients required for electroplating, and no unnecessary salts are introduced, as, for instance, when copper or zinc carbonate are first converted into copper and zinc cyanide by the use of alkali cyanide with the formation of soda. It will, therefore, be easily understood why the baths can be readily revived by the addition of trisalytes.

With all these advantages the trisalytes are bound to facilitate, expedite and improve the work of the plater.

Perth Amboy, N. J.

The waste heat in slag has attracted the attention of many inventors who seek to convert it into steam and apply the latter to low pressure engines of the turbine type. Walter G. Perkins and William H. Barker have recently been granted a patent (996,132) based on this idea.

The Important Factors in Blast-Roasting.

By H. B. Pulsifer

I.—Introduction.

The practice of blast-roasting which was inaugurated by the first Huntington-Heberlein process, originally of Pertusola, Italy, and first patented in the United States in 1898, has found so great favor with lead smelters that in some form or other it has now come to be part of the standard procedure at all large lead-smelting plants where a considerable proportion of the ore is available in the form of sulphides.

The success of the process is due to the fact that it is a good sulphur-eliminating process, that a great variety of ores are susceptible to the treatment, that the material is left in an ideal form for smelting in the blast furnace, and that the cost of the treatment is far less than the cost of any previously known method which would even approximately produce the same results.

The treatment of copper ores containing sulphur has been brought to considerable perfection as regards sulphur elimination in blast furnace, reverberatory and converter; this method is entirely inapplicable to lead ores in that exactly opposite conditions are necessary for the best work. In fact, should the uniformly quiet reduction and easy gas passage of a lead blast furnace be disturbed by local breakings through of the blast, such as might possibly represent the normal working of a copper blast furnace, the results are at once disastrous in that values are unduly lost by volatilization, the matte runs high in lead, and the slag will easily enough carry away twice the values it should.

On this acount any oxidizing influence whatever is precluded in the blast furnace, and every attempt is made to have the charge already fully prepared for the straight reduction when it reaches the furnace. Blast-roasting accomplishes the desulphurization and agglomerating in a way which leaves its product ideal for the blast furnace.

A close approximation to the original Huntington-Heberlein process still persists in certain localities where heavy galena ores are to be made ready for smelting; a modification involving pre-roasting but no addition of lime is widely used where pyrite ores form a considerable part of the sulphides. Further deviation pre-roasts the priming or igniting layer only, and finally, as at Midvale, Utah, no part of the charge is pre-roasted, but a fire on the grate ignites the mixed raw charge which is dropped upon the hot bed of burning fuel.

Although nominally considered of the best mechanical design and construction, the plants for this type of roasting have not always proven satisfactory in operation. Slight precedent and unknown demands may well account for the inability of the engineers to meet conditions where the costs of the mechanical operations and handling of materials have suddenly become the chief cost factor.

The introduction of the down-draft machines, at present represented only by the Dwight-Lloyd types, will unquestionably again make a general lowering of the cost of the roasting and at the same time again improve the quality of the product for its use as blast furnace burden.

The accompanying bibliography indicates the literature readily available to one interested in the subject. Unquestionably not only the industry at large but each individual plant involved, would receive much benefit if those most qualified were more free to honor the literature with their experience.

The author desires to express particular obligation to Mr. J. E. Greenawalt for the most painstaking instruction and helpful interest in the study of all branches of the subject.

Nearly all the references given in the bibliography have been studied either in their original or translated form; a few only have been seen in abstract.

Acknowledgment is accordingly freely made to each of the respective authors.

II.—Bibliography.

PATENTS

1. U. S. Patent 600,317, March 8, 1898. Thomas Huntington and Ferdinand Heberlein. By mixing lime with lead ores, and, after preliminary heating, forcing air through the hot mass, the ore is both desulphurized and sintered. The ore is first to be heated in a furnace and then transferred to another receptacle for the completion of the process.

2. U. S. Patent 705,904, July 29, 1902: Archibald Drummond Carmichael. By mixing gypsum with sulphide ores of lead he is able, after starting the reaction with heat, to prepare the ore for blast furnace work in one operation. "My invention consists, essentially, in dispensing with the preliminary roasting and in the complete desulfurization and cineration of the sulphides in the converter in one operation."

3. U. S. Patent 755,598, March 22, 1904: Adolf Savelsberg. It is found that by mixing limestone with the lead ores sulphides can be desulphurized in one operation. "The final product is a silicate consisting of lead oxide, lime, silicic acid and other constituents of the ore, which now contains but little or no sulphur and constitutes a coherent solid mass which when broken into pieces forms a material suitable to be smelted." He uses a layer of limestone, either above, or below, or mixed with the layer of fuel, to protect the grate.

4. U. S. Patent 786,814, April 11, 1905: Thomas Huntington and Ferdinand Heberlein. They improve their original process by quenching the preparatory roasted ore with water before finishing in the converter; find that it is not necessary to mix lime with the ore if the hot roast is quenched and combustion started anew in the converter. Their points of importance are pre-roasting, cooling, and then blowing in the converter.

5. U. S. Patent 808,361, Dec. 26, 1905: Herbert Haas. Patents a certain regulation of the blast or air supply as used in his sintering converter.

6. U. S. Patent 839,064, December 18, 1906: J. E. Greenawalt. Combines a porous hearth with drawing air and gas down through so as to collect and save values otherwise lost during roasting and ore-treatment.

7. U. S. Patent 839,065, Dec. 18, 1906: J. E. Greenawalt. In ore-treating processes the material is placed upon a porous bed and the products of roasting or ore treatment are drawn down through the bed. The illustrations and application relate to mechanically rabbled furnaces.

8. U. S. Patent 870,690, Nov. 12, 1907: Adolf Savelsberg. Patents a two-stage roasting with wetting of the charge between.

9. U. S. Patent 882,517, March 17, 1908: A. S. Dwight and R. L. Lloyd. In treating fine ores so as to roast and sinter them the surface from which the gases escape is restrained so that the whole mass is uniformly firm. The principles of sintering are elaborately expounded.

10. U. S. Patent 882,518, March 17, 1908: A. S. Dwight and R. L. Lloyd. The method of sintering with movable grate is devised. The grate carrying the bed of ore to be treated moves relative to the ignition, suction, feed and discharge; a continuous process.

11. U. S. Patent No. 916,903, March 13, 1909: F. D. Weeks. A blast-roasting machine.

12. U. S. Patents 916,391, 916,392, 916,393, 916,394, 916,395, March 23, 1909: A. S. Dwight or to A. S. Dwight and R. L. Lloyd. The three types of continuous machines, cylinder, annular table and straight line, are illustrated and described.

13. U. S. Patents 916,396 and 916,397, March 23, 1909: A. S. Dwight. In the first patent the ore is sintered between a grate and a restraining device covering the ore, for either continuous machines or intermittent units; in the second patent the upper surface is restrained by a layer of coarse ore.

14. U. S. Patent 942,052, Dec. 7, 1909: H. C. Bellinger. A blast-roasting furnace.

15. U. S. Patents 951,198 and 951,199, March 8, 1910: W. G. Perkins and M. L. Requa. A new machine and method for blast roasting.

BOOKS AND PAPERS.

The Mineral Industry under "Progress in the Metallurgy of Copper," by L. S. Austin, and under "Recent Improvements in Lead Smelting," by H. O. Hofman, since the development of blast-roasting, has given [illegible] abstracts of the more important papers appearing in the literature. The references are very complete and doubly valuable because of the comments of the accomplished reviewers. Most of the following papers are referred to in this publication, but the list has been brought up to date and each of the following is worthy of individual study:

[illegible] "The Lead Smelting Practice." By W. R. Ingalls. Eng. and Min. Jour., LXXXI, [illegible]

[illegible] "The Desulphurization Process." By Arthur S. Dwight. The Mineral Industry, 1907, XVI, 380.

[illegible] "Lead Smelting." By W. R. Ingalls. Mines and Minerals, 1907, XXVIII, [illegible] The Mineral Industry, 1907, XVI, 665. Describes blast-roasting at Murray and Midvale.

19. "Lead and Copper Smelting at Salt Lake, I and II." By W. R. Ingalls. Eng. and Min. Jour., 1907, LXXXIV, 527 and 575. Describes the plants at Murray, Midvale, and Garfield.

20. "The Dwight and Lloyd Sintering Process." By Arthur S. Dwight. Eng. and Min. Jour., 1908, LXXXV, 646.

21. "Treatment of Sulphide Ores by the Huntington-Heberlein Process." By L. S. Austin. Min. and Sci. Press, 1908, CXVI, 641. Gives cost of producing sinter in a 50-ton Huntington-Heberlein plant.

22. "Laboratory Experiments in Lime-Roasting a Galena Concentrate with Reference to the Savelsberg Process." By H. O. Hofman, R. P. Reynolds and A. E. Wells. Trans. Am. Inst. Min. Eng., 1908, XXXVIII, 126, also p. 935. A series of 17 tests blast-roasting galena with lime in charges of a little over 1 kilo each.

23. "The Production of a Converter-Matte from Copper-Concentrates by Pot-Roasting and Smelting." By George A. Packard. Trans. Am. Inst. Min. Eng., 1908, XXXVIII, 633.

24. "Lead Smelting and Refining at Trail, B. C." By A. J. McNab. The Mining World, 1909, Sept. 4. A very satisfactory account of the Huntington-Heberlein roasting is included.

25. In "Mines and Methods," 1909, I, 6, C. T. Rice gives an excellent description of the Midvale plant of the United States Smelting, Refining & Mining Company.

26. "The Behavior of Calcium Sulphate at Elevated Temperatures with Some Fluxes." By H. O. Hofman and W. Mostowitsch. Trans. Am. Inst. Min. Eng., 1909, XXXIX, 628. A valuable investigation, relating especially to the chemistry of the Charmichael-Bradford process.

27. W. Poole describes the treatment of Broken Hill ores in the Bulletin Sydney University Eng Soc., 1908, Nov. 11. Abs. Mineral Industry, 1909, XVIII, 484.

28. "Pot Roasting of Copper Ores in Australia." By S. Radcliff. Mining Science, 1909, LIX, 67. Abs. Mineral Industry, 1909, XVIII, 485. Original in the Australian Mining Standard.

29. "The Mining Industry in Queensland." By G. W. Williams. Eng. and Min. Jour., 1909, LXXXVII, 603. Abs. Mineral Industry, 1909, XVIII, 486.

30. "Trail Smelter and Lead Refinery." By J. M. Turnbull. Mines and Minerals, 1910, September, p. 121. An acceptable article which includes much material already previously given by McNab. (See above.)

31. "Notes on the Roasting and Sintering of Ores." By F. M. Smith. The Mining World, 1910, Sept. 10, p. 459. A short account of mechanical roasting and the Dwight-Lloyd installation at East Helena.

32. "Agglomerating Fine Ores and Flue Dust." By Herbert Haas. Eng. and Min. Jour., 1910, XL, 814. A rather general smelting discussion and a proposed blast-roasting plant suggested by the one at Torreon, Mexico.

33. "The Metallurgy of Copper in 1910." By L. S. Austin. The Mineral Industry, 1910, XIX, 181. Describes the Greenawalt process for roasting and sintering copper concentrates and flue dust at the Modern plant near Denver.

34. "Recent Improvements in Lead Smelting." By H. O. Hofman. The Mineral Industry, 1910, XIX, 436. Abstracts of the important papers appearing during the year are given as well as comments on the process of blast-roasting, especially the success of the Dwight-Lloyd machines. Exception is well taken to some of the statements asserted by Paul Richter which were based on his laboratory experiments with roasting. "Beiträge zur Theorie des Huntington-Heberlein Prozesses und der ihm verwandten Verblaseverfahren," published by Robert Noske, Borna-Leipsiz, 1909.

35. "Down-Draft Sintering Experiments." By A. W. Hahn. Eng. and Min. Jour., 1911, XLI, 1208.

36. "Midvale Plant of the United States Smelting Company." By Leroy A. Palmer. The Mining World, 1911, May 27. A good account of the roasting and sintering is included.

37. "Speisses and Their Beneficiation." By C. Guillemain. Eng. and Min. Jour., 1911, XLI, 858, from Metallurgie, VII, 19. An account of how speisses have been successfully blast-roasted to remove arsenic.

38. "Lead (The Metallurgy of)." By Henry F. Collins. Published by Charles Griffin & Company, Limited, London, 2nd Ed. 1910. Contains an excellent chapter on blast-roasting.

39. "Operations of the Doe Run Lead Company." By Albert H. Fay. Eng. and Min. Jour., 1910, LXXXIX, 610. Describes the operating of the Savelsberg converting plant at Herculaneum, Missouri.

40. "Recent Progress in Blast-Roasting." By H. O. Hofman. Trans. Am. Inst. Min. Eng., 1911, XLI, 739. See also discussion, p. 915, by James W. Neill. A fairly complete review, but blast-roasting at Garfield and Tintic was soon discarded and details at Murray and Midvale plants are not wholly accurate.

41. "The Sintering of Fine Iron-Bearing Materials." By James Gayley, Bulletin Am. Inst. Min. Eng., 1911, 56, 631. Records the success of the initial trying-out of the Dwight-Lloyd machine on iron flue dust and fine ore.

42. "Recent Progress in the Roasting of Sulphides." By Leon Guillet. Revue de Metallurgie, 1911, 8, T, August, pp. 561-605. An earlier and briefer paper entitled "Progresos de la Metalurgia del Plomo" by the same author appeared in the Revista Minera, Metalurgica y de Ingenieria, 1911, June 1, 8, 16, 24 and July 1, pp. 277, 292, 307, 318 and 330. Covers the developments in Europe, in particular the installation of the three annular Dwight-Lloyd machines at Bindsfeldhammer, near Stolberg, while some references are also made to American practice.

Note.—At the time of reading the proof, this February, we are able to add two recent papers on the subject: A. S. Dwight, in the *School of Mines Quarterly*, Nov., 1911, gives a good review of all roasting methods from the efficiency point of view; and an editorial correspondence in METALLURGICAL AND CHEMICAL ENGINEERING, Feb., 1912, gives a valuable account of the operation of the Dwight-Lloyd machines at Salida, Colo.

III.—The Chemistry of Blast-Roasting.

1. *The Elimination of Sulphur.*

According to locality and conditions the charge which it is desired to roast and sinter may consist of any of the intermediate mixtures between the limits of rich galenas on the one hand and nearly pure pyrite on the other. The general

experience, as gleaned from the literature, is that with rich galenas or high lead mixtures the charge, to be successfully blown, must be comparatively low in sulphur. The upper limit is given by some operators as 9 per cent, while with possibly somewhat lower leads other operators can blow mixtures with up to 12 per cent. With comparatively low lead in the mixture, the remaining sulphur being chiefly as pyrite or chalcopyrite, charges containing up to 20 per cent sulphur are successfully blown.

Evidently the two predominating factors as to the amount of sulphur admissible are, first, the fusibility of the charge, and, secondly, the form in which the sulphur exists. A charge which is as easily fusible as must necessarily be the case when the lead is present to the extent of 40 per cent or more, or which consists largely of leady matte, in both of which cases the sulphur to be removed must first be fully oxidized, must have the sulphur content already low for good results in a roasting pot. There is evidently no avoiding of this conclusion. In the installation of the three annular down-draft tables at Bindsfeldhammer, as described by Guillet in his paper, preroasting is first practised. With the pyritiferous mixtures, which are inherently more difficult to fuse, we also are favored with sublimation of the first easily discarded atom of sulphur in pyrite. This sulphur which is driven off by heat without supplying any heat by its oxidation is easily observable during the roasting of this class of material. With up-draft pots it is of little significance, but with down-draft sintering it is a source of much clogging of the pipes and of the fan if that be placed in close proximity to the unit.

The sublimation of sulphur is a condition to be met in the planning of down-draft construction, provided that pyrite may be a constituent of the charge, and in considering the heat evolution of the charge mixtures we may allow that a definite percentage of the sulphur will not be oxidized so as to supply its heat value to the raising of the temperature of the charge.

Experiments with 2-ton charges show that for the elimination of sulphur from leady copper matte by down-draft the best diluent is iron ore; silicious ore makes a somewhat more satisfactory sinter cake, but the sulphur in the product will be somewhat higher. Limestone makes a good diluent also, from the structural side, but the sulphur in the product is much higher than with silicious diluent. A matte containing lead, 22 per cent; copper, 15 per cent; and sulphur, 22 per cent, when diluted with an equal or large and varying amounts of limestone and a little silicious material, gave uniformly about 9.0 per cent sulphur in the product; silicious dilution alone gave good sinters with less than 7.0 per cent sulphur, while diluting with equal parts of silica and iron ore made a product, good in its physical properties, and containing only 4.0 per cent sulphur.

Repeated tests by Greenawalt have uniformly indicated that limestone is not a good diluent for pyritiferous charges. Other investigators have come to the same conclusion when using this kind of material.

The secondary reactions so prominent in the hand roasting of lead ores in reverberatory furnaces which furnish large quantities of sulphur trioxide are largely subordinated in up-draft roasting; with the still more expeditious results attained with down-draft work the production of sulphur trioxide is again diminished. The exact amount in the gases from down-draft units is not known to the author, although certain experiments indicate that it is very low, indeed. This is a most important consideration where the gases are to be diffused over cultivated areas or are to be neutralized and freed from the trioxide.

The volatilization of lead and silver values, once such a handicap to all roasting of lead ores in reverberatory furnaces, became of much less significance with the introduction of up-draft blast-roasting. Without a thought we charge into the pots ores for roasting which would undergo serious loss in a hand reverberatory; rich concentrates only will commonly be reserved for briquetting. With the advent of down-draft methods no reservation of ores on account of loss by volatilization will likely be required. Little data is as yet available, but there is every indication that the loss is quite insignificant. In ordinary pot or stall roasting the chief loss occurs because of the inevitable formation of blowholes and the overheating and burning which result to the charge about them. In down-draft work the formation of blowholes is automatically inhibited; at any point of too much heat evolution and consequent fusion the suction pulls down the melt and the air is choked off; nothing comes of it except delaying the operation of roasting.

Aside from this automatic inhibition of blowholes the charge is exposed to heat for a much shorter time than in the thicker charges using up-draft; instead of breaking out to a free surface the gases are filtered through the comparatively cool inert layers protecting the grate, some small portion of fines is made during the charging and discharging of the cake, but flue dust as such is not made to an appreciable extent in down-draft practice.

To obtain a prompt and satisfactory roast the required amount of air must have access to all portions of the ore mixture; that this may be possible the charge must be so constituted that air *can* circulate to all parts, and, even more important, the air must have access to all parts *until the required elimination of sulphur is accomplished.* On the one hand, the charge must not contain so little sulphur that combustion shall cease and the material becoming dry and powdery prevent the passage of air over a certain area, nor, on the other hand, dare the sulphur be so abundant that the charge shall become overheated and, falling into a pasty mass, effectually clog the area against further oxidation.

Independent observers have come to the same conclusion, that passing air *through* the mass of a charge to be roasted is many times more efficient than passing air *over* the same material, however well it may be stirred.

This is the chief factor in all blast-roasting; sulphur elimination demands the passing of air; for the easy passing of the air the charge must be so constituted that it will allow the air to pass both at the beginning of the operation and during the whole course of the operation.

It is not difficult to construct suitable grates for either up- or down-draft types of equipment, nor is it difficult to make the charge permeable to the influence of the draft. Originally the permeability of the charge is mainly a matter of its moisture content. Whether it is coarse or fine is no matter as long as the original moisture is appropriate for its physical condition. A charge of material, each particle of which is of ½ in. size, will pass air readily, whether dry or whether containing 2 per cent of moisture; a charge of slimy concentrates and flue dust may be almost impermeable, whether dry or whether muddy, yet there will be some definite moisture content, let us say 12 per cent moisture, at which, if the charge is first well agitated in a mixer and then put to sinter, the batch will hold its shape, be quite porous and allow the required amount of air to pass easily enough.

It has more than once been stated in the literature that batches were too fine for sintering; it is also recommended for charges too high in sulphur that considerably more water might be added to keep down the heat by its evaporation. The fallacy of either opinion may be quickly enough dispelled by a few, even small-scale, experiments.

2. *The Formation of a Sinter Cake.*

It so happens that those conditions which produce desulphurization by blast-roasting also leave the roasted product as a sintered mass. This has been characteristic of every effort and all methods or particular furnaces. The sintered product has been found remarkably desirable for lead blast furnace smelting; furnaces smelt rapidly and well using this kind of roast; it is so desirable that it is worth taking pains to provide a sinter cake firm and porous.

As has just been explained under Chemistry, the conditions

governing the passing of air account for the desulphurization the same conditions apply to the formation of the sintered cake, where the ore remains unroasted the product will be fines, where the heat has been too intense the material has fused together still carrying its sulphur and now in a massive condition, extremely hard and tough.

Irony materials, such as iron ores, may replace the silica for desulphurization but not for the production of a firm sinter. When iron ore would be added to the blast furnace charge along with the roast, for the production of a suitable slag it might be considered advisable to let the roast carry the iron in whatever excess should be necessary for the final slag. The conditions evidently regulating this refer both to this production of a firm sinter and to the question of the fine crushing of the materials. It would certainly appear poor management to crush iron ore, thereby making the sinter friable when silicious fines are already to be had by simply screening the available silicious ore which would otherwise be fed direct to the furnaces.

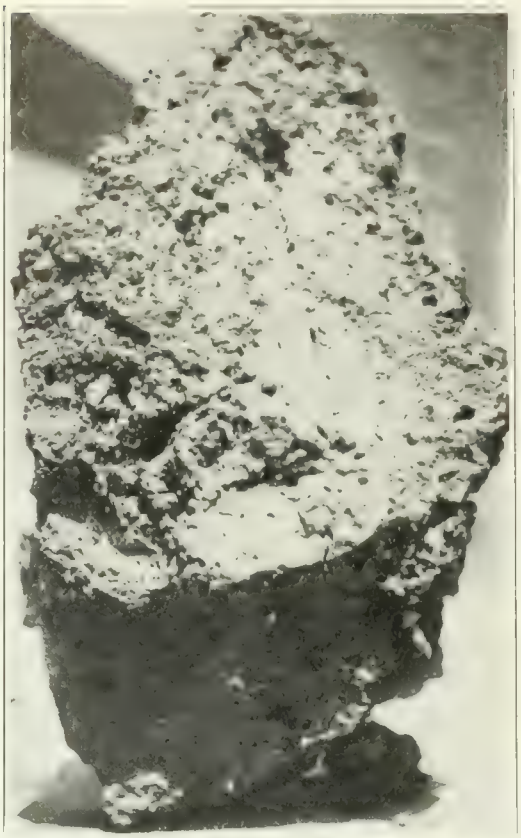

FIG. 1.—MASSIVE SINTER CHARACTERISTIC OF THICK CAKES AND UP DRAFT.

FIG. 2.—OPEN SINTER CHARACTERISTIC OF RATIO WORK WITH SUCTION DRAFT.

For the ores high in lead, above 40 per cent. and the sulphur reduced to about 9 per cent it has been found that if the remainder of the batch consists of approximately equal parts of silica, lime and iron the sinter will be of good structure and work well in the blast furnace. For the ores lower in lead the mixture to be sintered may well contain up to 30 per cent silica, a little iron ore not mattering much but addition of limestone being avoided.

The two following analyses will certainly produce matty sinters:

Insol.	Fe	Pb	S	Zn
22.0	17.8	23.0	18.6	4.3
20.5	28.8	10.1	20.4	6.0

The sulphur is so high that local fusion will take place and although the sinter will be firm and tough it will be massive in parts and contain layers or patches of matte.

Two batches for direct converting made up of concentrates, silicious ore and a little iron ore or other rather inert diluent analyzing as follows will produce excellent and cleanly silicious sinters:

Insol.	Fe	Pb	S	Zn
26.0	24.0	17.0	16.1	4.7
23.2	10.3	13.8	17.2	5.3

Given the conditions necessary for sulphur elimination, and enough heat generated to momentarily fuse the constituents, if enough silica is present to form a web-like skeleton other care is hardly necessary.

In large and thick charges there is always a particular tendency to heat retention and melting together. The thin beds made with down-draft equipment are easily superior in this respect.

Thin beds can not easily accumulate as much heat and with the best work the sintered cake should replace the original charge in almost its exact volume.

The sinter will be firm, cellular and porous, not containing any portions heavily slagged together.

These cakes should not be crushed in the heavy breakers which are required for "pot-roast" cakes but rather in suitable toothed rolls.

Hot charges as come from pre-roasting, either in reverberatory or mechanical furnaces, are extremely porous provided that the ore has been stirred and is not badly caked. The particles evidently touch without packing, exactly as when a cold, fine ore is moistened and mixed. In one case the particles are sticky and lightly held together because of their temperature, in the other case because the amount of moisture is exactly right. In all cases stirring and mixing must be done so as to lighten instead of packing the ore; the hot or moist ore once patted firmly together will be impermeable enough to any ordinary effort to pass air.

Following the original Huntington-Heberlein process that type of pot-roasting still begins the operation in the converters by blowing air up through a comparatively thin bed of red-hot pre-roast laid on a covering of clinker which protects the grate. The ignition starting afresh in the hot roast mounts through it and into the cold and moistened pre-roast or moistened "direct converting" mixture and soon accomplishes the desulphurization and sintering of the whole mass.

Obviously the cost of ignition by this method is nil, where preroasting is practiced.

Where pre-roasting is not practised the ignition of the charge comes from some outside source as from a mixture of fine coal, coke and pyrites as at the United States plant at Midvale, Utah (see papers by Palmer and others). After the grate has received a protecting layer of inert material, such as limestone or cold roast, the fire is applied in the form of hot and burning coal and coke, a slight blast is admitted, the pyrite is spread on, the charge is dropped on and the blast is increased.

Igniting is certainly a considerable item of cost when this method is used. In general, if the charge mixture itself does not ignite readily the cost is heavily increased. It is a pretty

sure method when enough fuel is thus used, almost any amount of water may be driven off or too dry charges will be sintered whether they support combustion themselves, or not. Other methods would be far cheaper for doing these kinds of work. An inherent difficulty with this method as with Huntington-Heberlein igniting is that results cannot be fully known until the cake has to be dumped.

A charge for down-draft sintering, which is composed of pyritiferous lead concentrates, fine silicious ore and other desirable diluent, if sulphur, silica, moisture and mixing are properly done and the section applied, will take fire immediately upon the application of a combustible material or a flame. Oil, sprayed from nozzles under pressure and confined over the charge with a hood, is the most suitable igniting agent yet found. The lighter oils possibly work a little better but partly refined or even thin crude oils are satisfactory.

A 2-ton charge with a surface approximately 5 ft. by 8 ft. may be ignited with a flame of atomized oil, sprayed from nozzles with a pressure of 90 lb., in 15 seconds. One minute is a long time to allow for such a flame to start even a poor charge; if the surface will not ignite sooner than this the heat will so dry the top that longer heating is useless.

Especially at night it is a beautiful sight to watch this sort of igniting. A bit of waste lights the oil as it is turned on, the suction draws down the flame, it roars a few seconds, is turned off, the hood is rolled away, exposing the whole surface, a half minute before cold, damp and inert, now seething with an intense combustion that quickly eats its way into the cake, leaving the exterior again black and dead but now hard and firm. Lacking unusual imagination the operation needs be seen for full comprehension. In case any spots are not well started they are best remedied by waiting a few minutes and then raking a little hot crust from other parts over the raw areas.

IV.—The Types of Roasting Units.

All the types of roasting units have been described in the literature; detailed descriptions, dimensions and operating methods may be found by referring to the individual papers. We shall concern ourselves here only with the principles involved and the cost of operation.

1. *Huntington-Heberlein Pots.*

This method of roast-sintering has gained a remarkable standing the world around, but is evidently yielding to the down-draft methods as at present solely represented in operation by the Dwight-Lloyd machines.

The particular points strongly in favor of the H. & H. method are large tonnage, ability to handle rough and ready charges and its adaptability to all sorts of ores and conditions.

The weak points are volatilization, massive and high sulphur sinters, large cost of pre-roasting, handling and breaking, production of considerable fines and poor working conditions.

Unquestionably a small plant may be rushed to a great capacity; 8-ton units can do fairly good work and turn out 16 tons of charge each per 24 hours, day after day. The product may be badly slagged and matted, sulphur may be high and much fines produced, but still tonnage holds high and roast is always on hand for the furnaces. This is an important consideration in any successful plant.

On the other hand, these very conditions are the weakness of the method. Any process equally reliable and of the same operating cost that does not volatilize several per cent of the lead, that does not make large quantities of flue dust and fines, that does not make massive and matted roast or that requires less attention and affords better working conditions, will be in line to ultimately supplant the process.

Up-draft plants are bad to work in. The slightest derangement of parts and the customary excess of blast over draft create a condition not alone uncomfortable, but one which the better class of labor is not prone to long endure. This is the smallest consideration in any plant, but in a careless moment of abounding fresh air and ignorance of the future we dare assert that it is a point against the H. & H. process in particular and against all up-draft sintering in general.

Metallurgists have asserted that the free and unrestrained upper surface of the charge in an H. & H. pot is the source of the blowing over of the dust, the volatilization, the blowholes, and the slagging and matting. It is not to be denied that the top of the charge is opened by the force of the blast, and that the upper portion is constantly poked and dug into by the man in charge in his efforts to prevent the blowholes; certainly the top layers remain more or less unagglomerated to the last, and must be poured off for succeeding charges. In spite of all this what ground is there to suppose but that this is not other than a result of a condition which develops in the bottom of the charge and finally breaks out at the surface? Local fusion and inequalities in the mixture inevitably induce a concentration of the blast into channels which wend their way up to the surface. The ideal condition described by Professor Hofman is certainly far from being realized in those plants where the miniature volcanoes break out an hour or two after charging, and must needs be continually demolished from then until the cake is declared to be finished. If the moisture is right and the mixing is thorough the blast will start right; it is then merely a question of how soon the oxidation is gaining around the edges and in cones throughout the interior. Long observation impels me to believe that most of the roasting is according to the latter interpretation.

The large cakes made in the regulation converters are difficult to reduce to the proper size for smelting. While still hot the cakes are tough and sticky and bad to handle, their whole interior is commonly red-hot, much water is needed and labor wastes itself. The 24-in. by 36-in. crushers commonly supplied for the crushing are also too small for the chunks, which ought to drop in easily. Breaking by dropping or letting a weight fall on the cake makes much fines, and is tedious.

Pre-roasting widens the range of the method in that it can treat higher lead and higher sulphur ores for any stated tonnage. The costs per ton of output, however, are certainly higher than for direct converting, and which method is the more economical will then evidently depend on the abundance and character of the ore supply. Against this process we must also charge the necessity of maintaining a briquetting plant if that is kept on account of ores too valuable to trust in the pots.

Pre-roasting is by no means an operation so cheap that its cost may be neglected. I have yet to be convinced that it is expedient to use it except in exceptional cases where the ore supply is remarkably one-sided.

During 284 working days the mechanical pre-roasting furnaces of an H. & H. plant required 3330 tons of coal and produced in conjunction with the pots 24,023 tons of product; direct converting material was also made to the extent of 22,580 tons, but the igniting material came from the same furnaces. If we allow for ⅛ of this direct product as having been pre-roasted and the cost of coal as $3.00 per ton the cost will be:

$$\frac{24{,}023 + (22{,}580 \div 8)}{3330} \times \$3.00 = \$0.372$$

If we reckon power at	$0.06 per ton
labor at	0.06 per ton
fuel at	0.37 per ton
incidentals at	0.02 per ton
	$0.51 per ton

will be the cost of the pre-roasting.

If this amount of original sulphide diluted with ¾ of its weight of silicious and other material, ½ of which is to be briquetted at an equal cost, were direct converted over a primer of the pre-roast, the difference in cost might be roughly estimated thus:

Pre-roasting and blowing 100 tons at $0.95	= $95.00
Direct converting 175 tons at $0.75	= 131.25

If this charge of $30.25 be divided by 2, since half of the material would be briquetted at the same cost, it leaves $18.13, which, reckoned against the 37.5 tons of fine material, is evidently a charge of 48c. per ton. This is a considerable tax against the ore, but it must be considered that it is for the benefit of the entire blast furnace charge, let us say 600 tons. It amounts to some 3c. a ton thus disposed of, and the question is, has it benefited the entire charge to that amount. The answer is that taking the briquettes and fines from the furnace burden has made far more than this small benefit. The increased rate of smelting alone will amount to more than that. We must also admit the long campaigns, the general good behavior and excellent reduction of furnaces running fast and free.

If we wish to estimate the cost of the fuel for pre-roasting as charged against the entire output of the roasting plant,

(3330 ÷ 46,603) x $3.00 = $0.21 per ton of product.

The cost of labor in a plant of this sort may be given as approximately according to the following table:

Labor per 24 hours, 200-ton capacity plant:

No. of Men.	Duty.		Price.	Shifts.		Amount.
1/3	Foreman,	@	$3.00	x 3		$3.00
1	Hoistman,	@	2.35	x 2		4.70
1	Pot Boss,	@	2.50	x 2		5.00
1	Craneman,	@	2.50	x 2		5.00
1	Fireman,	@	2.10	x 3	=	6.30
2	Trammers,	@	2.50	x 2	=	10.00
2	Pokers,	@	2.10	x 2	=	8.40
1	Bed Mixer,	@	1.90	x 2	=	3.80
1	Charge Man,	@	2.10	x 2	=	4.20
5	Laborers,	@	1.00	x 2		10.00
				Total,		$69.40

$$\frac{60.40 \times 284}{46{,}603} = 0.423$$

Operating cost of department, per ton product:

Labor	$0.42
Fuel	0.21
Power (estimated)	0.10
Bedding	0.05
Supplies (estimated)	0.01
Repairs (estimated)	0.06
Total	$0.85

At 400 tons capacity the cost should be not far from $0.69 per ton.

2. *Savelsberg Converters*

Details of this little used process are to be found as indicated in the list of papers:

Ingalls, *Eng. and Min. Jour.*, 1905, LXXX, 1067.

Fay, *Eng. and Min. Jour.*, 1910, LXXXIX, 610.

Hofman, *Trans.*, Am. Inst. Min. Eng., 1910, XLI, 745.

It appears that with the high lead in the mixture the addition of limestone has no particular influence to retain sulphur. It is to be noted that before blowing the sulphur must be diluted to a comparatively low figure. The amount of limestone added is not very large, and that even then the tonnage is not much, if any, exceeding that of the H. & H. process. From the accounts of the manner of feeding the mixture into the pots the item of the cost of labor will be fully normal. As well be discussed more at length further on, the success of any roast-sintering process will depend largely on the mechanical and other engineering which is incorporated as a part of the process. From the published descriptions of this process it has little along this line to recommend it. From the account given by Hofman if the sulphur in the original charge is reduced from 11.20 to 2.30, and if 10 per cent loss in weight be allowed, this is equivalent to an elimination of about 82 per cent. This is exceptionally good work, and it is to be regretted that further details of operation and cost are not available. The latest *Mineral Industry* reports that these converters are being replaced by Dwight-Lloyd machines.

3. *Bradford-Carmichael Converters.*

This process, although reported as no longer used, is interesting both from its chemical and engineering side. Sulphuric acid was made from the gases generated, which were unusually rich in sulphur dioxide.

The cost data as supplied by Ingalls is in particular to compare with the cost of the other methods:

Labor	$1.80 per 8 hour
Gypsum	2.40 per 2240 lb.
Coal	8.40 per 2240 lb.

	Per Ton Ore.
0.25 ton gypsum	$0.60
Treating gypsum	0.48
Drying ore and gypsum	0.12
Converting	0.24
Breaking sinter	0.12
0.01 ton coal	0.08
	$1.64

4. *Converter Stalls at Midvale, Utah.*

Aside from the manner of igniting the blowing of these converter stalls is quite similar to the blowing of H. & H. pots. The remarks made about the principles involved in the volatilization, production of flue dust, creeping up of the burning zone, blowholes, massively slagged and matted product, etc., apply to one as to the other. Possibly the material used at Midvale may have, in general, been lower in lead than even the "direct converting" as used in the H. & H. process, and if the sulphur may at times have been lower they are probably favored with long periods when sulphurs can be considerably higher, due to this very fact of low lead.

On a basis of 270 tons a day produced, the following details are probably a close approximation of the labor requirements:

1 Shift.		Per Ton.
1 Bin man, at $1.80	$1.80	$0.020
1 Scale man, at $2.25	2.25	0.025
1 Motor man, at $2.00	2.00	0.022
1 Mixer man, at $2.25	2.25	0.025
1 Overhead tram man, at $1.80	1.80	0.020
1 Ram man, at $2.25	2.25	0.025
4 Poker men, at $2.00	8.00	0.089
2 Clay men, at $2.00	4.00	0.045
1 Crane man, at $2.75	2.75	0.031
1 Crane chaser, at $1.80	1.80	0.020
2 Fire tenders, at $2.00	4.00	0.044
2 Crusher tenders, at $1.80	3.60	0.040
1 Hoist man, at $2.25	2.25	0.025
1 Stall boss, at $2.50	2.50	0.028
½ Services of foreman, at $3.50	1.75	0.019
1/3x1/3x2 Hopper cleaners, at $1.80	0.40	0.004
	$43.40	$0.482

Three shifts will require 3x43.40, or $130.20.

For tonnages between 200 and 350 tons a day about the same number of men will be required to operate the plant; with the less tonnage a few men might be laid off, and with the higher tonnage a very few extra men might be required. We can then say that for a plant of this type the cost for labor will vary with the tonnage within these limits:

200 tons	65.1c.	280 tons	46.5c.
210 "	62.0c.	290 "	44.9c.
220 "	59.2c.	300 "	43.4c.
230 "	56.6c.	310 "	42.0c.
240 "	54.3c.	320 "	40.7c.
250 "	52.1c.	330 "	39.5c.
260 "	50.1c.	340 "	38.3c.
270 "	48.2c.	350 "	37.2c.

These various items may be segregated:

Supplying	$0.112
Operating	0.207
Crushing and loading	0.116
Supervising	0.047
	$0.482

Total operating cost

Labor	$0.48
Fuel for igniting	0.11
Power (estimated)	0.09
Supplies (estimated)	0.01
Repairs (estimated)	0.00
	$0.78

Using the labor figure of 38c. for a 350-ton basis makes a total of $0.68 when producing that amount of product per 24 hours.

Evidently the figures as given apply to operating costs only. The cost of labor is by far the greatest single item. This item, in any plant, is one quite accurately determinable and little subject to bookkeeping manipulation. The item of fuel is also comparatively easy of estimation, but is much smaller in its amount. The item of power may vary somewhat with the manner of accounting, but it is believed that the figure as given is sufficiently close. Supplies form a small but distinct item. The item of repairs, or of repairs and maintenance, as might be called, is the most difficult of any given to estimate properly. Into this item enters the efficiency of the carpenters, mechanics, boilermakers, blacksmiths and electricians, all of whom are beyond the jurisdiction of the department, and may run up costs independently of the good efforts of the roaster foremen and the men directly under them. Here also enters the method of accounts. Is the department to take a certain proportion of the maintenance crews or actual hours in service? Certain repairs may even be long postponed for a low item, the men meanwhile enduring inconvenience and by their good will or from their needs keeping operations going.

It is to be noticed that these costs are for all costs whatsoever in the blast-roasting department. As it will cost practically nothing to get the product into the furnace storage bins the original unloading charge is put against the smelting department, and costs begin with getting the ore out of the bins. As the material must necessarily be sampled whether roasted or not this cost, with which might be included any trifling screening cost, is also charged outside of the department.

5 *Dwight-Lloyd Sintering Machines.*

These machines, which are becoming fairly numerous about the country, cannot be spoken of from personal knowledge. Their operating cost is commonly stated to be from 50c. to 75c. per ton of product. As to exactly what items this includes little information is given.

The principles of the operation are certainly all well taken, and the actual cost will evidently depend largely on the mechanical arrangements of supplying, mixing, feeding and disposing of the product.

In general it may be said that simple devices and methods are most favored by smelter operators. Lead smelteries in particular often try out good and standard equipment, afterwards reverting to cruder methods.

By referring to the items of cost, as given for roast-sintering at two large plants already mentioned, it will be seen that the actual cost of labor for operating is a comparatively small item, the cost of supplying and crushing and loading being greater. Operating cost is a strong point with the new machines, and if this evident extremely low cost is not otherwise compensated for they will inevitably gradually attain better standing. Repairs and maintenance are a cost item which will be found interesting as the machines begin to wear.

Besides being of continuous operation and large capacity, the draft is induced by suction from below and the charge lies in a thin cake. These are all strong points, and indicate a great future for the method.

(To be concluded.)

The Flare of Furnace Walls.

BY CARL HERING.

In an article on the "Thermal Insulation of Furnace Walls," published in the February issue of this journal, page 97, some curves were given for determining, in a very simple way, the loss in watts through furnace walls of different sizes, thicknesses, thermal resistivities and temperature drops, based on the rigidly correct formulas; they, therefore, take into account the flare, which for thick walls becomes important.

These curves were given for spherical and cubical furnaces as these shapes are the only two general types for each of which the results can be given by a single curve; moreover, they are the most rational shapes; for others not differing too greatly from these, the results would probably not be far wrong if one assumed for the calculations a spherical or cubical one of about the same inside surface as that of the particular one under consideration.

The calculation with the aid of these curves is partly graphical and partly arithmetical. The curves replace the tedious calculation of the geometric mean of the inside and outside surfaces (the square root of their product) which is the rigidly correct section to use for determining the insulation resistance, hence the loss of heat.

The purpose of the present article is to give the analytical formulas, their deduction and their modifications. It sometimes becomes necessary to use them beyond the range of the curves or when the calculation involves each of successive layers of different resistivities; even when the insulating material is the same, its resistivity may be appreciably different at different temperatures, as was shown in that article, hence different layers may have to be calculated separately. Moreover, it may be desirable to allow for the resistance of joints also, between different layers, and these may have greatly different areas in different parts of a thick wall. As the loss of heat through furnace walls is by no means small, it may often be desirable to endeavor to predetermine it as carefully as the conditions warrant.

In such more intricate cases it is far simpler to calculate the resistances of the various parts, add them together, and find the loss once for all from this total, instead of calculating the flow each time for each part in accordance with the older method.

Some slight complications arise in the use of such formulas due to the calculation of the geometric mean, and to the difference between the relative and the actual wall thickness. The complications due to the latter may be avoided by a clear and concise statement of the formulas, and those due to the former by not reducing them to what the mathematicians would call their "simplest" forms, as taught in text books, but by using instead incompletely reduced forms which, though quite as correct, are much simpler to use. What the mathematician considers the simplest form is not always the simplest one to use in practice. In the present case, by retaining a quantity which could have been eliminated and is therefore theoretically an unnecessary complication, the calculations become in fact much simpler.

Let R be the total thermal resistance from the inside to the outside, either of the whole furnace wall or of any one or more layers; it will simplify calculations to state this in thermal ohms,* and this is assumed here. Let r be the resistivity (specific resistance) also in thermal ohms. Let d be the actual

*A thermal ohm is that thermal resistance through which one watt will flow when the difference of temperature is one centigrade degree.

inside diameter, or the inside edge if a cube; D the actual outside one; L the actual wall thickness. Either inches or centimeters can be used provided they are used consistently throughout.

The rigid law says that the mean cross-section of a flaring body like that of a sphere or cube is the geometric mean. Hence if s and S are the inside and outside surfaces the correct mean will be the square root of $s \times S$.

Hence for a sphere, whose surfaces are πd^2 and πD^2,

$$R = \frac{rl}{\sqrt{\pi d^2 \times \pi D^2}} = \frac{rL}{\pi dD} \qquad (1)$$

The quantity L could be eliminated because it is a function of the two diameters, namely, $2L = d + D$, but it simplifies the calculations to retain it.

Similarly for a cube

$$R = \frac{rl}{6dD} \qquad (2)$$

These are rigidly correct; they are based on the assumption that the resistivity r is the same throughout.

In many cases the calculations are still further simplified by using the curves mentioned above. In these the thickness is given *relatively* to the inside diameter or edge; let this relative thickness be l, then $l = L/d$ or $L = ld$. This quantity l is, of course, independent of whether inches or centimeters are used.

Substituting this in (1) for a sphere

$$R = \frac{rl}{\pi D} \qquad (3)$$

but as $D = d + 2ld$

$$R = \frac{r}{d} \times \frac{l}{\pi + 2\pi l} \qquad (4)$$

Or for cubes (2)

$$R = \frac{r}{6d} \times \frac{l}{1 + 2l} = \frac{r}{d} \times \frac{l}{6 + 12l} \qquad (5)$$

Hence the heat flow in watts, $W = T/R$, when centigrade degrees and thermal ohms are used, is for spheres

$$W = T \frac{d}{r} \times \pi (1 + 2l) \qquad (6)$$

and for cubes

$$W = T \frac{d}{r} \times (6 + 12l) \qquad (7)$$

The curves above referred to give the values of the last factor in each of these, which is the part that is the same for all sizes, resistivities, or temperatures; hence they give the watts when T, d and r are each unity. The curves were calculated from these two formulas.

Hence by multiplying the watts given by the curves for any particular value of l, by the actual inner diameter or edge, and dividing by the particular resistivity of the material in thermal ohms, gives the watts per degree; multiplying this by the temperature drop gives the total watts.

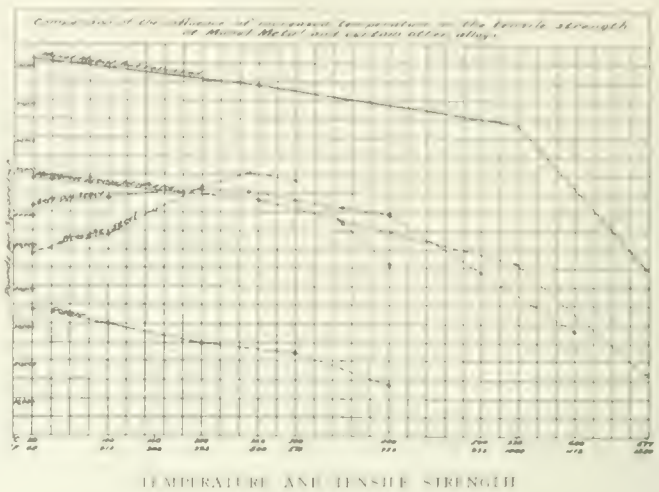
The number of "watts per degree," just referred to, is in fact the thermal conductance in thermal mhos* and is the reciprocal of the thermal resistance in thermal ohms.

Influence of Increased Temperature on the Strength of Certain Metals and Alloys.

The strength of various metals and alloys at ordinary temperature is well known and the selection of the proper-size piece of a suitable material is comparatively easy. Little is known, however, of the strength of these materials at higher temperatures and it is only by extended investigation of pieces tested while at these temperatures that a safe basis for proper selection may be obtained.

*Thermal Resistance and Conductance; the Thermal Ohm and Thermal Mho. METALLURGICAL & CHEM. ENG., January [illegible], p. 13.

A reference to the accompanying curve will show the relation that the strengths of certain alloys at ordinary temperature bear to their strengths at higher temperatures. These results show that Monel metal retains over 80 per cent of its elastic limit and tensile strength at 1000° Fahr., while at that temperature steel retains only 71 per cent, manganese bronze



TEMPERATURE AND TENSILE STRENGTH

60 per cent, and copper has lost 60 per cent of its strength at 750° Fahr. This is accompanied in the Monel metal with no less, indeed with practically no change, in ductility.

The Solidification of Iron Castings.

In the course of a recent lecture before the London Branch of the British Foundrymen's Association Prof. T. Turner, of Birmingham, said it was well known that iron castings were smaller than the molds in which they were formed, and the shrinkage had to be allowed for in making the patterns. He used the term "solidification" as including all the changes which took place between the pouring and the removal from the mold. Shrinkage varied with the hardness of the iron and with the rapidity of chilling. Total shrinkage was ascertained by casting a standard bar between iron yokes and comparing the measurement of the distance between those yokes and the length of the cold bar. During the process of solidification in the mold, cast-iron underwent expansion at several stages, and the total shrinkage was the algebraic sum of the several expansions and the uniform contraction.

With an extensometer recording temperatures and expansion simultaneously it was shown that ordinary soft, phosphoric gray irons expended three times and that those three expansions all occurred after the bar had become solid from the ordinary point of view. The expansions reached their maximum degree respectively at about 1100° C., 900° C. and 700° C —points which seemed to correspond with the separation of primary coarse graphite, the phosphorus eutetic, and pearlite.

The lecture was illustrated by diagrams and photo-micrographs showing the stages of crystallization of cast-iron and the nature of the three expansions, and explaining the difference between the effects of crystal thrust at the beginning of the solidification and that of the subsequent expansions.

Calorimeters.—An interesting bulletin has just been issued by the Schaeffer & Budenberg Mfg. Company, of Brooklyn, N. Y., on three new types of calorimeters. No special skill is required in their use on the part of the operator. The first is the "throttling calorimeter" for determining the amount of moisture in saturated or supersaturated steam, its operation being based on the measurement of heat. The second is the "separating calorimeter," which serves the same purpose, the percentage of water being determined, however, by mechanical separation of the water from the steam. The third is a "coal calorimeter" for determining directly the calorific value of coal.

New York Meeting of the American Institute of Mining Engineers.

THE 102nd meeting of the American Institute of Mining Engineers was held in New York City on February 19, 20, 21. The immense general interest taken in this meeting was evidenced by the excellent attendance from all parts of the country. All business and professional sessions and social functions were equally well attended. While the number of those who registered was 175, a fair estimate of the actual attendance is 250.

Business Meeting.

The meeting was a huge success in every sense and its keynote was harmony. Harmony prevailed at the business meeting which was held on the morning of Tuesday, February 19, when it had been thought that opposing views might clash on the framing of the future policy of the Institute, especially on the proposed amendments to the Constitution as to the reclassification of members with a raise of annual fees and the change of the name of the Institute to "American Institute of Mining and Metallurgy."

That the "insurgents" were in majority at the present meeting, however, became evident at the election of directors. There were two tickets in the field. That of the "insurgents" received 45 votes of those present and 881 proxies, that of the "regulars" 29 votes of those present and 310 proxies (these being the mean figures for the three candidates respectively). The directors elected are Messrs. E. B. Kirby, Geo. C. Stone, and Chas. F. Rand. On motion of two of the gentlemen on the other ticket the election (irrespective of proxies) was made unanimous.

For the election of officers and councillors, there was only one ticket in the field and the following gentlemen were elected: Prof. James F. Kemp, president; Messrs. Benj. B. Thayer, Karl Eilers, and Waldemar Lindgren, vice-presidents; Messrs. Jos. W. Richards, John H. Janeway, Jr., and Sidney J. Jennings, councillors; Dr. Joseph Struthers, secretary.

Dr. Ledoux, as chairman, expressed his gratification at the great interest that had been taken and at the spirit of har-

PHOTOGRAPH TAKEN AT BANQUET OF AMERICAN INSTITUTE OF MINING ENGINEERS

These controversial matters did not come up for discussion and decision, since a motion was proposed by Mr. J. Parke Channing, to have all the matters referred to a special committee of five, very carefully selected as to its membership so as to be representative of the whole Institute. The scope of the investigation to be carried out by this committee is very broad. It will report to the Directors of the Institute and an adjourned business meeting of the Institute will be held on June 3, 1912, or on such later date as may be mutually agreed upon by the committee and the directors. At that meeting the proposed amendments to the Constitution are to be finally considered. This committee consists of Messrs. Corning, Kemp, Ledoux, Wm. H. Nichols, Jr., and Stone.

This peaceful solution of the controversy which had been originally proposed by the "insurgents," found just as much favor with the "regulars" and indeed with everybody, so that Mr. Parke Channing's motion was unanimously carried.

mony, of absolute good feeling and of community of purpose exhibited by all of the members.

Social Functions.

The convention was informally opened on Monday evening, February 19, by a social meeting and smoker of the members at the rooms of the Institute, which had been nicely decorated with palms and flowers. There was good feeling all around. An address of welcome was made by Mr. Benjamin B. Lawrence, as chairman of the local committee.

Mr. Charles Kirchhoff, the retiring president of the Institute, presented an elaborate address on the aims and ideals of the Institute, laying particular stress on the differentiation of the duties of the Instiute toward its several types of members—mining engineers, geologists, and metallurgists.

Prof. James F. Kemp followed with a very interesting and humorous talk on some of his adventures in the Canadian

Rockies and in Mexico. This address was illustrated by lantern slides, some of which were very amusing.

On the evening of Tuesday, February 20, a very enjoyable subscription dinner was held at the Hotel Plaza. It was well attended and was graced by the presence of many ladies. Mr. Charles Kirchhoff, as toastmaster, was excellent in the pointed brevity and quiet humor of his introductions.

The first speaker was Director George Otis Smith, of the U. S. Geological Survey, who spoke of the ideals and the career of the Survey.

Mr. W. L. Saunders gave in a most interesting speech some of the impressions which he got from his recent trip around the world. He emphasized that the industrial supremacy in the world is now passing over to Germany and to the United States and spoke in glorifying terms of the engineering capabilities of the German people, especially in mechanical engineering and engine building. The Germans are a practical people, they take nothing for granted; whenever they find anything they try to improve on it. As to the labor problem, cheap labor is not the foundation of success in manufacture. In Germany the price of labor has gone up rapidly in recent years in proportion with efficiency. It is efficient labor that really counts. Mr. Saunders concluded with some remarks on the tariff problem as the most important question now before the American people, but he thought that it would be a great mistake to take the tariff wall down all at once.

Dr. R. W. Raymond made an eloquent address, as only he can make, on the mining engineers' wives and the mission they faithfully and untiringly fulfill.

Colonel Alexander M. Hay, of Toronto, exhibited clever literary ability by discussing in a decidedly witty address in rhymes the problem of "latitude," with special reference to a famous controversy concerning the discovery of the North Pole. "There is no latitude for liars at the Pole."

The concluding speech was made by the Secretary of the Canadian Mining Institute, Mr. R. Mortimer Lamb, who discussed the work and career of this Institute.

Sintering of Fine Iron-Bearing Materials by the Dwight-Lloyd Process

The first professional session was opened by President Kirchhoff on Tuesday afternoon. It was chiefly devoted to a series of papers on agglomerating and briquetting fine materials.

The first paper dealt with the "sintering of fine iron-bearing materials by the Dwight-Lloyd process," the author being Mr. J. G. Klugh, of the E. & G. Brooke Iron Company, of Birdsboro, Pa., at which plant the Dwight-Lloyd process is in actual successful operation. In the author's absence the paper was presented by Dr. G. W. Maynard. (Mr. James Gayley's former paper on his application of the Dwight-Lloyd process to iron ores and concentrates was discussed and commented upon in our Vol. IX, page 431.)

According to the principle of the process, the finely divided iron-bearing material to be sintered is intimately mixed with the amount of carbon requisite to produce the sinter. This mixture is then moistened and deposited upon the machine in a uniform layer, the upper surface of which is ignited by a small flame of intense local heat, and the combustion of the intermixed carbon is effected in a progressive downward course by a current of air flowing in the same direction through the permeable mass. The energy from the combustion of each particle of carbon is expended and utilized directly upon the adjacent particles of iron-bearing material, agglomerating them into a coherent sinter.

In other words, the Dwight and Lloyd sintering machine is a piece of chemical apparatus in which to carry out the reaction between the oxygen of the continuous supply of air and the solid combustible material of the charge. The former is maintained in a zone of regular and continuous supply moving in the direction of gravity. The latter is, of course, intimately mixed with the material to be sintered. It logically follows that the capacity of the machine is limited by the weight of carbon burned per unit of time. It has been found that an amount of carbon equivalent to 8 per cent of the weight of the ore to be sintered furnishes ample heat for the production of the sinter. Carbon in the mixture in excess of 8 per cent performs the wasteful and deleterious functions of (1) consuming proportionately longer time for its combustion; (2) raising the temperature of the sinter produced to its fusing point, thus enveloping unconsumed carbon, and (3) raising the temperature of the grate bars and other parts of the machine. Besides which, the minimum consumption of carbon, consistent with maximum production and most desirable quality of product, is desirable for economical reasons.

From a given material, properly mixed with the correct percentage of fuel, the character of the sinter produced depends wholly upon the material itself, being unaffected by the speed of sintering or velocity of air supply; but its amount per unit of time depends upon the rate of combustion of the intermixed fuel, which, in turn, depends upon the rate at which the oxygen is brought into contact with fresh fuel, as the inert products of combustion are taken away by the action of the fan.

Thus the permeability of the bed of material, and the pressure drop between the atmosphere outside and that in the wind-box determine—other conditions remaining constant—the rate of the production of sinter.

Permeability is largely influenced by the moisture added. The function of the water is not entirely understood. Primarily it causes a temporary agglomeration of the particles of the materials, thus preventing them from passing through the grates. The voids in the bed are then larger, offering less resistance to the gas current. It must be borne in mind that the amount of added moisture is not a given percentage by weight, but the quantity required to produce a certain degree of plasticity. For instance, to a fine hematic there could be added 15 per cent by weight of water before the material would cohere properly, but with magnetite, 4 per cent of added water produces the equivalent degree of plasticity. The regulation of this phase of the process, which is doubtless very important, has as yet been determined by rule-of-thumb only. This is done very well by ordinary workmen after a small amount of practice, especially upon a given material.

The diagram, Fig. 1, shows the relative arrangement of the product and crude material in the active sintering zone. The rectangle represents a vertical cross-section through the pallets over the wind-box. The sinter and ore mixture are seen to be separated by an imaginary line beginning and ending at two

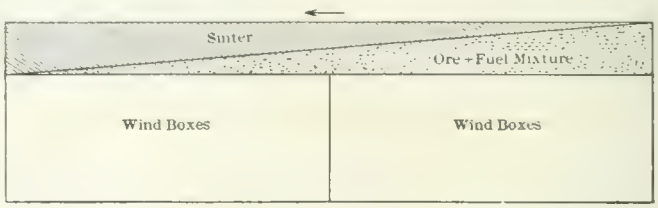


FIG. 1.—DIAGRAM SHOWING ARRANGEMENT OF MATERIAL IN THE ACTIVE ZONE, I. E., THE PALLETS OVER THE WIND BOXES

respective zero points. This is about the state of all materials. When high-carbon materials are sintering the combustion of the carbon proceeds downward, progressively. Should high carbon follow low carbon directly, the only adjustment necessary is to slow down the speed of the pallets, allowing greater time for burning out the excess of carbon. The only condition under which residual carbon is left in the sinter is when the temperature of the sinter in the upper part of the bed is raised, so as to render it incipiently fluid, and permit it to envelop small amounts of carbon. This only occurs when the carbon is excessively high, say, about 20 per cent.

As to the desulphurization effected there have been practically no high-sulphur materials treated which were not brought down as low in sulphur as the best Lake ores. No special adjustment or preparation of the ores is necessary to effect desulphurization; the sulphur is eliminated simultaneously with the sintering. The desulphurization is not dependent upon the form or quality of the ore. Pyrites cinder has been brought down from 4.41 to 0.07 per cent, while magnetites have been lowered in sulphur from 3.50 to 0.15 per cent.

An analogy between the sinter made has been suggested by the Dwight and Lloyd process and mill cinder. No such comparison is practicable. The two materials are wholly different in origin and appearance. Whenever mill cinder or puddle cinder has a small amount of entrapped gases, producing pores, the walls of the pores are glazed and impervious to gases. In fact the material is a glass, which has been completely liquid. The Dwight and Lloyd sinter, made under normal conditions, has never approached the liquid state, and hence its particles are united by plastic coherence of their surfaces, and the cell walls have the microscopic porosity of easily reducible ores.

Microphotographs were given in the paper to show that there exists a positive distinction between the various forms of mill cinder and Dwight and Lloyd sinter. However porous the mill cinder may be, it can never approach in reducibility the product under consideration. Mill cinder is a satisfied chemical compound, only giving up its oxygen at high temperatures, and then affording a minimum area of contact for reaction of reducing gases. Dwight and Lloyd sinter is a physical agglomeration of material treated, being bonded of particles of original size.

Several thousand tons of sinter have been produced at the Birdsboro plant and used in the blast furnace. At all times the sinter has shown itself a superior and beneficial material of the blast-furnace charge. By reason of variations in the ore mixtures, no actual figures of the fuel saving effected through the use of the sinter are available; but several times as much as 10 per cent of easily reducible Lake ores has been replaced by sinter, and the management unhestitatingly declares that taking off the ore and putting on the sinter has the same influence on the fuel consumption as would result from taking off entirely that amount of ore burden.

At no time has there been any reaction in the furnace resembling that produced by mill cinder. When mill cinder is used with a burden of a high percentage of magnetic ores, a scouring action is often noted—especially when the mill cinder is put on to the amount of 12 per cent mass in one. There has never been at the Birdsboro furnace any scour action or descent of unreduced oxides since this sinter began to be used. According to all practised indications and theoretical considerations, there seems no doubt that a complete burden of Dwight and Lloyd sinter might be used advantageously.

The iron blast furnace stands on a high plane as regards metallurgical efficiency, but there are yet vast opportunities for improvement. Not the least of these lies in the due preparation of ores and fluxes prior to charging.

Mr. Gayley, in his Institute paper, quoted from Schinz's book on "The Action of the Blast Furnace" (1871) the following sentence: "A chemical reaction can only take place between two bodies, however great their affinity, if they are in intimate contact with each other; and the rapidity of this action will be so much greater the more numerous the points of contact are."

Mr. Gayley's purpose in this quotation was to lay stress upon the advantage of the Dwight and Lloyd sinter over other materials in giving a greater area of contact to the gases in the reducing zone. But the importance of this law is equal if not greater in its application to the reactions between solids in the fusion zone. And this is where blast-furnace practice seems farthest from the ideal at present. Materials are charged in groups of tons, which can only perform their proper functions by combinations between minute particles. It then seems only logical to say that, if greater intimacy of arrangement were provided between the bodies forming the slag, a distinct advantage would be gained, in that a slag of the desired chemical composition would be continuously formed in the zone of fusion. In present practice, there is an intermittent production —first, of a basic and then of an acid slag—all finding their way into the hearth, and making up a final fair average, but certainly not constituting, in the strict sense of the term, a continuous chemical operation.

The natural consequence of submitting to zones of varying temperature mixtures of varying melting points is a discontinuous and disproportionately wide zone of fusion. This source of irregularity is probably the source of many slips, scaffolds and other disturbances in furnace practice.

As a possible remedy for these conditions Mr. Klugh suggests a wider application of the Dwight and Lloyd sintering process. Let us assume, as a hypothetical case, a mixture containing all-fine ores of any specific burden (say, 40 per cent of the entire ore charge) and the flux of the entire burden (crushed to pass 10-mesh and under) to which the proper amount of carbon is added and sinter is produced. This sinter now contains: (1) The iron partly metallic and partly as either oxide; (2) the gangue and flux, not necessarily combined, but intimately associated and free from all CO_2. While the line is thoroughly calcined it differs radically from a separately calcined line, in that it is so agglomerated with other materials as to remain solid, instead of shaking and disintegrating.

The advantages to be expected from the use of such material in the blast furnace are:

A.—The solid mixture, containing uniform slag constituents, will carry them unseparated to the bosh, where their function will be performed continuously, instead of interruptedly (by "running ahead" and segregating).

B.—All the CO_2 having been eliminated, the solution of carbon by ascending CO_3 will be avoided.

Hence from there actions, $CaCO_3 = CaO + CO_2$; $CO_2 + C = 2\,CO$; there will be effected a saving of carbon equivalent to 12 per cent of the weight of the stone, assuming conditions of 1150 lb. limestone per ton of pig; 96 per cent of $CaCO_3$ in limestone; 85 per cent available carbon in coke, then:

1150 lb. limestone $= 1150 + 96 = 1104$ lb. $CaCO_3$.

$1104 + 0.12 = 132$ lb. carbon saved.

$132 \div 0.85 = 154$ lb. coke per ton pig saved.

C.—An increased reducibility of the iron so treated. (This has been conservatively estimated as 5 per cent better than the best available ore.)

D.—As a larger portion of the slag-forming constituents will have already been combined an amount of carbon representing difference between the heat for fusion and the heat of formation will be saved.

E.—Uniform delivery of properly porportioned materials to the different zones.

There has been set a numerical value for only the first case as it is almost universally conceded that the carbon solution factor is equal to the theoretical. Upon presenting this proposition to a well-versed student of blast-furance conditions he stated, "the furnace which does that will double its output." The author does not claim such sanguine advantages as this, but feels that an advantage would be gained far in excess of the expense of sintering the materials.

Materials otherwise regarded as unfit for the blast furnace may be readily and cheaply converted into a product most desirable for that purpose. For instance, as considerable flue dust carries an amount of carbon in excess of that required for sintering its own iron-bearing constituents, this may be used by mixing the flue dust with blue billy or magnetites, thus giving a product of uniform, cellular composition without cost for fuel.

In the extended discussion which followed Dr. Maynard gave the following figures of cost for the process. The first cost

intendence, etc., up to finished erection; the cost of two such

cents for labor charge, 3 cents for repairs, 24 cents for power, and 5 cents for ignition, or a total of 41 cents per ton.

Messrs. Richards, Schniewind, Eilers, Howe, Dwight, Chance, Vogel, Keith, and Cowles also participated in the discussion in which the chemistry of the sintering reaction and the reasons for the reduced fuel consumption were dealt with in some detail.

As to the production of fines in handling sinter produced by this process, Mr. Dwight stated that when properly conducted there should be no fines. There are less fines in the case of magnetite than in that of flue dust.

Very interesting samples of sinters produced in practice at Birdsboro by the Dwight-Lloyd process were exhibited

Agglomeration of Fine Materials.

A paper by Prof. Walter S. Landis, of Lehigh University, gave a concise review of the general subject of agglomeration of fine materials, including both the molding and the sintering processes. In the absence of the author it was presented by Dr. J. W. Richards.

Fine materials have heretofore been wasted to a greater or smaller extent. A list of such fine materials includes:

1. Fuels, fines being produced in the mining and preparation and in the storing of coal and lignites.
2. Concentrates from ore-dressing operations.
3. Fine ores.
4. Flue dust. Prof. Landis estimates the flue dust made by the iron blast furnaces of this country in 1910 as 3,500,000 tons, carrying at least 35 per cent of iron. At a low value of 4 cents per unit of iron, this dust costs almost $50,000,000 for its iron content alone, besides the $1,500,000 worth of coke in it.
5. Scrap metal, such as filings, chips.

The processes of agglomeration of fine materials are divided by Prof. Landis into two groups.

In the first group certain properties in the material are utilized for producing the desired coherence without addition of any foreign binder. Thus ores carrying soluble salts, clay, easily hydrated compounds, etc., may be moistened with water and molded into form and dried. But while coherence is thus produced, the product has the great disadvantage that on heating to a temperature sufficiently high to drive off the water, the briquets fall to pieces.

Pressure greatly assists in developing the cohering power of many materials. Sometimes the best results are obtained with dry materials, sometimes a certain amount of moisture is necessary. The pressure so far used in such processes runs up to 2000 atmospheres.

Heating to a high enough temperature also brings materials into a pasty or semi-fused state so that they sinter into a more or less firm mass. When carried out in a rotary kiln, the process is called nodularizing. This same property may be taken advantage of by molding the material into briquets, using only a slight pressure to insure filling the mold, then burning the briquet so formed at a temperature that will insure cohesion. (Gröndal.)

Finally a combination of pressure and sintering may be employed.

In the second group which includes the greatest development of the briquetting process, a foreign substance is used as a binder. Some of the binders which have been employed are clay, lime, ground slags, natural and Portland cements, waterglass, kieselguhr, carnallite, tar, pitch, asphalt, petrolemum, sulphite residues, napthaline, parafine, molasses, resin, starch, and other materials.

The operations of this second group are divided into three sub-classes: (a) Processes in which the binder is mixed with

in which a binder and pressure are used together, with a subsequent heat treatment.

Prof. Landis thinks not enough attention has always been paid to the selection of a binder for the particular case at hand. Too often is the intrinsic cost of the binder itself considered to be the main item in its selection, the subsequent cost it entails in passing through the smelting or refining furnace, being entirely overlooked. The waste-product possessing binding power may become very costly if it entails the production of an extra amount of slag to be smelted, or introduces in the furnace product a small amount of impurity which is difficult to remove afterwards.

Pressure increases the effectiveness of all binders, enabling one to obtain the desired results with the use of a minimum of extraneous material.

Finally the physical properties which a briquet should have are briefly summed up.

Sintering and Briquetting of Flue Dust.

A paper on the "sintering and briquetting of flue dust" was presented by Dr. Felix A. Vogel, of New York City. In the United States flue dust usually contains 20 per cent of coke and more than 40 per cent of iron. Estimating coke to be worth $3.25 per ton, and iron-ore 7 cents per unit, a ton of flue-dust, unless made available, represents a loss to the furnaceman of $3.50 per ton. This accounts for the first efforts to recharge the flue-dust into the furnace, either by moistening it down with an excess of water, or mixing it with clay to form balls or pulp, or treating it with limewater. These methods, however, have been practically discarded, as they failed to produce the desired economies.

The author enumerates the different conditions which must be fulfilled in an agglomerating process which is to be successful for the recovery of all the values in the blast furnace. Working along such lines American and European metallurgists have followed two different lines. In the United States it has sufficed to save the iron-content only, though not in the best possible form, while abroad the endeavor has been to make a high-class product for further use.

The author briefly reviews the different agglomerating and sintering processes which have been employed in this country, especially nodulizing in a rotary kiln, the Huntington-Heberlein process, the Gröndal briquetting process, the Dwight-Lloyd process, and the Greenavalt process.

Abroad the briquetting of flue dust has been more attractive than sintering. The lime process mixes the flue-dust with from 5 to 10 per cent of hydrate of lime and, after briquetting the material is exposed to the air for a certain length of time, so that a carbonate is formed which is the binding medium. This binder will eventually act as flux and replace a certain amount of stone. The process, while having decided advantages, is quite cumbersome and costly, as the briquets must dry from two to four weeks under cover.

The pioneer process uses sulphide pitch (obtained from the sulphide pulp-mills) as a binder. It is an organic substance, rich in carbon and hydrocarbons, which will burn readily and thus increase the caloric value of the material. The flue-dust is pressed into briquets with from 4 to 8 per cent of sulphide pitch; they are quite hard and give fair results, but the process is expensive.

The Ronay process does not use a binder. The flue-dust is submitted to a very high pressure in a specially-constructed type of hydraulic press; the resulting briquets can be handled immediately and have proved very satisfactory. The process requires an expensive plant, however, increasing the operating cost.

The Schumacher process does not use what may properly be called a binder, but is based on the latent cementing actions existing in fresh flue-dust and which are made active by the

per cent of magnesium chloride mixed with fresh flue-dust and from 6 to 10 per cent of water, pressed into briquets, will create a strong reaction, noticeable by the considerable heat developed; the briquets will be perfectly set and hard within a few hours. The process is very simple, an ordinary pug-mill being used in which to mix the material, which is subsequently pressed into briquets in a toggle-press and then loaded on cars to allow them to set.

Some flue-dust will react so strongly that a large amount of ore or coke-breeze may be added to the briquets; in these cases the flue-dust acts as a binder.

The Schumacher process requires an inexpensive plant and the cost of manufacturing is low. It is extensively used abroad and has replaced some of the other methods. The briquets of all-agglomerated materials have given most satisfactory results abroad and highest returns and values to the blast-furnace operators.

There were some very interesting exhibits of products of the Schumacher process.

In the discussion which followed Dr. Schniewind referred to a process used at the Krupp works in which granular blast furnace cinder high in lime is mixed with flue dust, subjected to superheated steam, and briquetted. Dr. Vogel stated that this process is no longer in use.

As to the use of chloride of magnesium, Dr. Vogel stated that it is used in Germany because it is a cheap by-product of chemical factories. In this country chloride of lime is used. As to the cost of the process, this was given as 40 to 65 cents per ton including royalty, in German and Belgian practice; in this country it is estimated as 20 to 30 cents. As to the nature of the catalytic actions, Dr. Vogel thought that three different chemical actions occurred, first cementing, second, oxidation of lower oxides, and third, hydration.

The Schumacher Briquetting Process.

A paper on "the Schumacher briquetting process" was presented by Dr. Jos. W. Richards, of Lehigh University, who had studied the process in operation at the works of the Cambria Iron Company, in Johnstown, Pa.

Discovered in 1908, the process rests upon the observation of Dr. Schumacher that blast-furnace flue-dust, while possessing of itself no binding or cementing properties, acquires strong cementing properties if mixed with a very small amount of certain salt solutions, the amount of which is so small that the resulting cementation appears to be rather by catalytic action of the salts added than by the mass action of such chemicals. To be more specific, fresh blast-furnace flue-dust mixed with from 5 to 10 per cent of its weight of magnesium chloride or calcium chloride solution, that is to say with from 0.25 to 2 per cent of its weight of magnesium chloride or calcium chloride, acquires the property of setting within a short time, from 15 to 60 min., and forming a hard cemented briquet. Alkaline solutions appear to have no action such as described, and they even interfere, if present, with the action of the magnesium and calcium solutions.

When treated in this way the flue-dust briquet sets very hard, apparently from pure excess of cementing and setting-power. It is, therefore, possible to mix with the flue-dust a considerable proportion of inert ore or like material, which has no setting power by this process, and thus to make a compound briquet containing large quantities of ore mixed with flue-dust, but in which the flue-dust may be regarded as the cement or binding material. A particularly strongly cementing flue-dust will carry as much as three times its weight of fine ore or the like, and yet produce a satisfactorily strong briquet.

The Cambria Steel Company have installed at Johnstown, Pa., a small plant consisting of two presses, with a combined capacity of 250 tons of briquets per day. One of the presses is of the mechanical type, with hydraulic safety-regulator; the other is a Ronay hydraulic press. The first makes briquets, the size of an ordinary fire-brick, the latter makes briquets cylindrical in shape, 8 in. high and 8 in. in diameter, and using considerably higher pressures than the former.

As seen in operation early this month, the warm flue-dust from the dust-catchers was stored in one hopper, while fine Mahoning ore, containing from 10 to 12 per cent of moisture, and quite cold, was stored in another hopper. A rotating feeding device formed a stream of these materials, passing into the mixing-trough with ordinary spiral, into which at the same time was run a 30 per cent solution of calcium chloride, the flow of which was regulated by a hand valve. The trough fed the mixture directly into the hopper of the press. The flue-dust was warm, approximately at 90 deg. C.; the ore was ice cold; the solution was cold. The mixture fed to the press was just warm to the touch, the bricks going from the press were decidedly hot and steaming, and where loaded into the car they were quite hot to the touch and steamed vigorously.

This heating of the mixture as soon as compressed into the briquet is a characteristic of the process, and is an index of the rapid chemical reaction taking place which results in the cementing of the material.

The pressures used on the two presses seen were 550 lb. per square inch on the Brück.-Kretschle press and 1250 lb. per square inch on the Ronay press. The first press consumed 35 hp, with an output of 7 tons per hour; the second press 25 hp, with an output of 4 tons per hour.

The flue-dust carries from 18 to 20 per cent of coke, which is all carried into the mixture, said mixture being 70 of ore to 30 of flue-dust. There is from 5.5 to 6 per cent of coke in a finished briquet. The saving of this coke, 20 per cent in weight of the flue-dust used, represents sufficient value to pay for the entire cost of the briquetting of the dust. Undoubtedly the coke thus enclosed in the briquet acts on the ore in the furnaces, and reduces it with at least as great an efficiency as the "green" coke put into furnace. Therefore, if the furnace has sufficient smelting power, other things being equal, this coke of the briquet may be estimated as saving at least an equal weight of coke to the furnace.

As to physical properties, a briquet made of flue-dust, absorbed 11.5 per cent of its weight of water, representing 27 per cent of voids, a very satisfactory porosity.

Briquets one day old, hard dried, tested for compressive strength, gave a minimum of 445 lb. per square inch (31.8 kg. per sq. cm.).

Several hundred tons of these briquets were already in the ordinary furnace bins, ready for use in the furnaces, and appeared to have stood transportation to that point and dropping 10 to 20 ft., and also subsequent action of ice and snow for several weeks without deterioration; only a few were broken, and but little dust was made.

The operation of producing briquets in this manner, from flue-dust and fine ores, appears to have attained the maximum of simplicity, the operation consisting merely of mixing with solution and pressing into shape. Estimates of probable cost, if the operation were carried out upon a scale such as would suit a large blast-furnace plant, yielded as the outside figure 30 cents per ton, inclusive of depreciation, repairs, and interest on plant.

The paper elicited considerable discussion. Dr. Richards discussed the possible rationale of the process. It works on flue dust, but not on iron ore itself. Nor does it work on silica or alumina. But it works on chemically pure iron oxide. Pressure is necessary and the greater the pressure the harder the setting. It would seem that only at the points of contact the cementing action takes place. As a possible explanation of the catalytic action, Dr. Richards proposed a certain cyclic process based on the fact that calcium chloride hydrolizes.

Dr. Howe accepted this cyclic-process explanation as reasonable, but thought it could be somewhat simplified. He thought that all pure speculations on the best mechanical conditions of briquets carried no weight, but only experience on actual fuel consumption.

The question of the observed heating of the briquets and other points of the chemistry and thermochemistry of the process were the subject of some further comment by Mr. Dwight, Dr. Howe, Dr. Schniewind, Mr. Cowles, and Dr. Richards.

Gröndal Briquetting Process

A paper on the Gröndal briquetting process was then presented by Mr. Nils V. Hansell.

It was in 1899, when Dr. Gustav Gröndal was manager for the Pitkaranta Iron Works in Finland, that he built his first channel kiln for the briquetting of iron ore concentrates. Similar kilns had been used previously for the burning of clay bricks, but for the adaptation of the process to the treatment of iron ores and for the gradual development of a modified type of kiln suited to this special purpose, the honor belongs to Dr. Gröndal.

Since then a greater number of kilns have been built both in Europe and in this country. At present, there are sixteen plants in Sweden with together about 35 kilns and a briquetting capacity of about 400,000 tons a year. In Norway, there are three large plants—Sydvaranger with 8 kilns, Salangen with 4 kilns, and Dunderland with 4. In England 12 kilns have been built, all treating pyrites residues and blue billy. Italy has one plant, Spain has two, and in the United States there are six plants in operation or construction. In Canada the first one is being built by Moose Mountain, Ltd., for the treatment of magnetite concentrates.

The Gröndal furnace can briefly be described as a channel furnace, through which the ore, pressed into bricks, is transported on flat cars which form a continuous movable platform through the furnace. The furnace is heated by means of gas introduced through the raised arch at a distance from the entrance end of about two-thirds of the furnace length. The flat cars are usually built of structural steel with firebrick tops and are furnished on each side with flanges dipping into sand troughs. They are often built with overlapping ends so that when they are pushed against each other in the kiln, they separate completely, the upper part of the kiln, through which the gases pass, and the lower part, in which are the trucks and the wheels. The furnace walls are built double, with an outside wall of red brick and an inside one of fire brick; the two being separated by an air space, which assists in lowering the heat losses by radiation, and at the same time permits the walls to move independently of each other in expanding and contracting on account of changes in kiln temperature when the furnace is started and stopped.

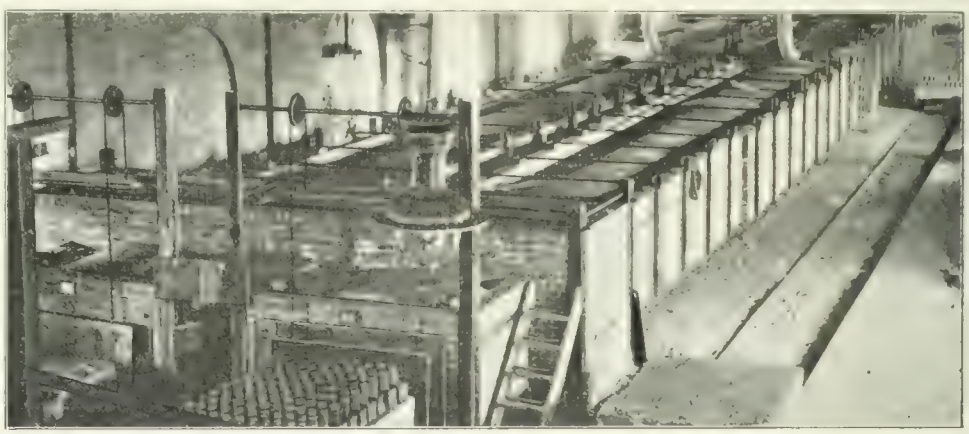

FIG. 2.—INTERIOR VIEW OF A TWO-KILN GRÖNDAL BRIQUETTING PLANT.

For obtaining the necessary temperature, almost any kind of fuel that has sufficient calorific value can be used. In Europe, the rule has been to use producer gas except at some places in Sweden, where the furnaces are built at iron works. There, a mixture of blast furnace gas and producer gas is burnt. Blast furnace gas alone is too diluted, so that the high temperature required for their action cannot be obtained unless it is enriched by some producer gas. When it is available, however, it is economical, as the coal consumption in the gas producer can thereby be cut almost in half. In this country, crude oil is used at two plants and natural gas at two. Local conditions govern the choice of fuel.

For different fuels and for different ores the construction of the kiln must be somewhat modified, although broadly the design is governed by the same principles. In the first third of the kiln the briquets are preheated by the escaping combustion gases; they pass through zones of increasing heat as the cars are pushed forward. In the combustion chamber the heat is maintained at about 2500 deg. F. When the briquets have passed the combustion chamber, they gradually pass through the cooling chambers, into which cooling air is blown by means of a fan. When they leave the furnace they are cooled off sufficiently to be unloaded directly into railroad cars. The arch over the cooling chamber is double and in some installations is made of corrugated cast-iron plates. Through the space between the double arches the air that is to be used directly for the combustion passes. On reaching the burners or the combustion chamber it has a temperature of 400 deg to 600 deg. F. The outgoing combustion gases, when reaching the stack flue, generally have a temperature of 350 deg. to 500 deg. F. It can be seen that the furnace is built on the regenerative principle and that its heat efficiency is high. The walls, as have been said, are double, and the arch is usually covered with 8 in. or 10 in. of sand, so that radiation losses are low.

Mr. Hansell then discussed in some detail the chemical reactions which take place during the passage of the ore through it. As a rule, regardless of their original composition, the briquets are discharged as a peroxide of iron (Fe_2O_3). If the ingoing ore is a hematite, it is gradually dissociated to Fe_3O_4 as the ore passes toward the combustion chamber. In a nearly white condition, it is here met by a current of highly heated air. This gives the ideal conditions for a rapid conversion from Fe_3O_4 to Fe_2O_3. Here lies the secret of the Gröndal process. Briquets at a temperature of 2400 deg. or 2500 deg. F. are met by air of high temperature. The oxidation is almost instantaneous. Thereby an appreciable amount of heat is liberated, to the benefit of heat conditions in the combustion zone.

A quick oxidation of the Fe_3O_4 produces a blue crystalline Fe_2O_3. A slow oxidation will give a product that is earthly, amorphous and reddish in color. From this it is clear that it is necessary to keep a high temperature in the combustion zone. The color and condition of the discharged product tells whether the furnace is run properly. Dark blue, firm, and strong briquets indicate a right temperature; loose and reddish briquets a temperature too low.

When the ingoing material is a magnetite, it is probably oxidized to a certain degree on its way toward the combustion zone. This oxidation is probably followed by a dissociation as the briquets enter the hotter part of the furnace, but the Fe_3O_4 so formed is again oxidized to Fe_2O_3 before being cooled off and discharged. This last re-oxidation is so complete that the analyses usually show over 90 per cent Fe_2O_3 of the total iron oxide in the briquet.

It is probably these chemical reactions which account for

the agglomeration and the great strength of the briquets. In the re-oxidation of the lower oxides of iron, diminutive crystals of hematite are formed, growing out on the surface of each ore grain in the briquet. These small crystals interlace with each other or grow together, forming a strong bond between the grains. If the ore is not crushed fine enough or consists of rounded pebbles, the intergrowing effect may not be obtained, and consequently the resulting briquets will be loose and easily disintegrated. Such was the case with tests with the concentrated product from St. Lawrence magnetic sands. It was found necessary to pass a part of the iron sand through a grinding mill in order to get some fine material to fill the voids between the larger pebbles. With pyrites residues there has been the same experience. It is futile to try to briquet cinder from lump pyrites without first grinding it so as to pass, say, 20 mesh, if strong briquets are desired.

The briquets in passing through the furnace are desulphurized. At Bayonne cinder with 2 or 3 per cent sulphur is discharged with about 0.03 per cent.

A number of Gröndal briquets have been tested as to their suitability for blast-furnace and open-hearth use.

Last year a low-grade magnetite was crushed and concentrated in a large commercial test. A part of the concentrate was briquetted at Bayonne, N. J. Of the product about 7 tons were shipped in an open-bottom dumper car to Youngstown, Ohio. Here they were dropped in unloading from a trestle 30 ft. high onto an iron floor. A screening test of the unloaded material gave through a ½-in. screen 8.84 per cent of the total mass. These fines gave the following results at the sieve test:

On 8 mesh	69.70 per cent
On 20 mesh	16.66 per cent
On 40 mesh	4.55 per cent
On 60 mesh	0.81 per cent
On 80 mesh	0.80 per cent
On 100 mesh	0.60 per cent + 0.06 per cent
Through 100 mesh	6.66 per cent + 0.16 per cent
Total	99.78 per cent + 0.22 per cent

The porosity of the briquets, being the ratio of voids to the total volume of the briquet, is always over 20 per cent. This is a strong point in their favor, as it aids in making them easily reducible in blast-furnace operations.

It is the rapid reduction of the briquets in the blast furnace that has made them so popular in Sweden; 25 to 50 per cent of briquets in the burden of charcoal blast furnaces of that country has been demonstrated to reduce the charcoal consumption per ton of pig iron by 15 to 25 per cent. Fifty per cent of the briquets in the burden gives the best charcoal economy. In Sweden 500,000 to 600,000 tons of pig iron are produced yearly. As 300,000 to 350,000 tons of briquets are reported for the same time, containing in average 64 per cent iron, which corresponds to about 200,000 tons of pig iron, or about one-third of the total pig iron production of the country. This means a yearly saving for the country of 400,000 cubic meters of charcoal.

For a furnace in Belgium using imported Swedish concentrate briquets in a mixture with calcined Bilbao spathic ore the following figures were given: With 70 per cent of briquets and 30 per cent Bilbao ore in the burden, the coke consumption was reduced to 1760 lb. per ton of pig iron. With all Bilbao ore it had been 2398 lb. The iron content of the Bilbao was 50 per cent, of the briquets 65 per cent. The output of the furnace was increased 20 to 25 per cent, with a corresponding saving in wages and general charges.

Concerning one plant in this country it was stated that at Mayville the coke consumption in the blast furnace has recently been considerably reduced by their use. The briquetting plant there has been in operation so short a time that it is too early yet to expect authoritative figures.

For use in open-hearth furnaces, the briquets are eminently fitted, being rich in iron, free from noxious substances, in lump form, and of sufficient weight to sink through the slag cover.

Finally some practical details of the running of a briquetting plant were given, together with notes on improvements in detail which are being made with every new installation.

Fuel consumption is low. In plants treating magnetic concentrates the amount of coal used in the gas producers averages 7 per cent of the weight of the briquets, and there are plants in Sweden using as little as 5 per cent. At a plant in this country where pyrites residues are briquetted and crude oil is used as fuel, the oil consumption is stated to be 15 gal. per ton, which corresponds to approximately 10 per cent. It is obvious that if the ore is heavy, as magnetic concentrates are, the relative percentage of fuel used will be lower than when ore that contains a great amount of combined water and other volatile matter is treated. With such ore a shrinkage in weight of 15 to 20 per cent has to be taken into consideration.

Mr. Hansell had a fine exhibit of briquets made by the Gröndal process.

In the discussion which followed, Mr. Alfred H. Cowles said that the larger the furnace is made the more effective it is and the longer is its life. The enlargement in design represents progress made for this process in this country. Mr. Hansell stated that in Europe larger furnaces are also now being adopted.

Electrostatic Concentration.

A paper by Mr. HENRY A. WENTWORTH, of Boston, Mass., dealt with the electrostatic concentration or separation of ores. The subject has already been dealt with at some length in our Vol. III, pages 181, 1905 (Blake-Moscher process) and in Vol. VIII, pages 295 and 636, 1910 (Duff process), but Mr. Wentworth's paper contains considerable interesting new matter.

Electrostatic separation of ores in its present form is generally known as the "Huff process" from the name of Charles H. Huff, of Boston, Mass., through whose constant and persistent labors (with the invention of Clinton E. Dolbear as a basis) the successful commercial process embracing separative machinery and the various electrifying devices have been developed step by step, and the finances for the long period of development provided, and the method finally established and recognized throughout the world as an important and successful addition to the ore-dressing department of metallurgy.

The permanent field-success of electrostatic separation began in 1908 with a 20-ton Huff experimental mill built specially for the purpose by the American Zinc, Lead & Smelting Company, in Platteville, Wis., a plant which was a success from the start and was gradually increased as the market conditions warranted to 100 tons daily capacity of concentrates. Much credit is due to the management for their initial venture, and for their assistance in applying the process to field use.

Prior to 1908 electrostatic separators had been installed and operated (but for a comparatively short time, however) in a number of places; some under the patents of Mr. Dolbear by himself and associates, and some under the patents of Lucien I. Blake and Lawrence N. Morscher, by W. G. Swart, mining engineer, of Denver, who has always been a courageous advocate of electrostatic separation.

Due to the difficulties experienced in the generation of the electrical charges, the primitiveness of the separators, the wooden construction instead of iron as at present, the lack of control of the electrical fields and other difficulties overcome by the later inventions of the Huff Electrostatic Separator Company, electrostatic separation did not gain favor during those early field endeavors.

Without going again into details of the principle of electrostatic separation, it may simply be recalled here that it depends essentially on two principles.

First, there is the fact that two bodies charged with the same kind of electricity (either both with negative charges or both with positive charges) repel each other, while two bodies

charged with opposite electric charges (one with a positive and the other with a negative charge) attract each other. This is illustrated by the well-known old experiment in physics where an electrified rod is brought close to a suspended pith ball. The pith ball is first attracted, clings for a moment to the rod, and is then vigorously repelled. As the rubber rod approached the pith ball a charge of opposite kind, so called, was induced on the side of the pith ball nearest to the charged rod, and as unlike charges of electricity attract one another and as the pith ball was very light, it moved to the rubber rod. But pith, though not a good conductor of electricity, does, because of the moisture contained, conduct electricity appreciably, and it soon became as a whole charged similarly to the rubber rod, and away it flew.

The second fact of fundamental importance is that different materials have different electric conductivities with

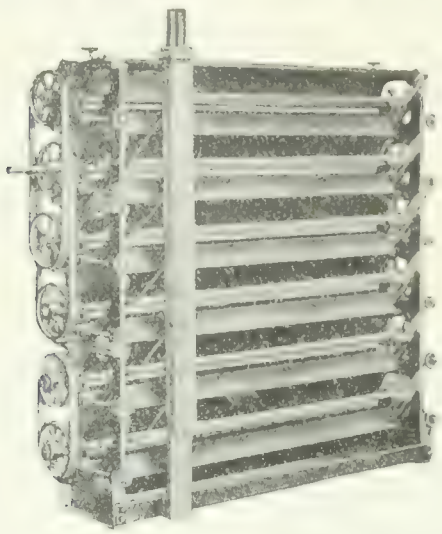

FIG. 3.—ELECTROSTATIC SEPARATOR.

the result that they require different lengths of time to be charged electrically. Assume that a mechanical mixture consisting of readily conducting and poorly conducting minerals (such, for example, as grains of copper and grains of sand) is dropped onto a metallic plate charged to a high potential. Immediately upon contact with the plate the better-conducting minerals become charged to the potential of the plate and are thrown vigorously from it. The poorer conductors require a much greater time to reach the electrical condition of the plate and therefore, if they are not given time to reach this condition, due to being removed from the plate, a separation is obtained. This method was utilized in the first simplest form of electrostatic separator.

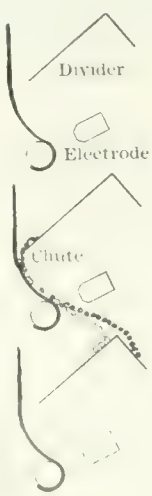

FIG. 4.—ELECTROSTATIC SEPARATOR.

Two types of electrostatic separators are now in common use. A type consisting of six separating fields and a feed is illustrated in Fig. 3, which does not, however, show the large feed-hopper and the heavy base. The entire machine, with the exception of the attaching rod and the insulator made of metal, is electrically grounded, so that all portions which come in contact with the ore are metal and all parts which the operator is likely to come in contact with are grounded so that the operator gets no electric shocks in touching the machine. As it is desired to pass a thick sheet of ore through the separators, there is more or less interference of particles at each separating roll; hence it has been found advisable to use several rolls in succession, each contributing a part toward the complete separation. This is especially necessary in those cases in which it is desired to keep the ore coarse at the beginning, and thus have many attached particles to be re-ground. In order to have all the metallics come in contact with the separating surface a number of contacts at different angles is necessary. In this machine the only moving parts are seven steel rolls revolving in babbitted and greased bearings, so that the power necessary to drive the separator itself is extremely small.

Fig. 4 illustrates a diagrammatic sketch of a second form of separator which is finding particular favor in the separation of washed zinc-iron middlings below 20 mesh, which flow very readily. The advantage of this type is that there are no moving parts whatever, except the feed roll, and therefore there is a minimum of wear and required power. Not all material, however, will flow sufficiently freely without external assistance to be applicable to this type of separator.

The limits of size of particles which can be successfully treated by the present forms of Huff machines is from 6 or 8 mesh down to the limits of granularity of the material. Those slimes which are so cohesive that they do not move uniformly over inclined chutes cannot as yet be successfully handled. It is possible that this can be overcome by a special design of feed or separator. In Utah a table middling is being treated wherefrom the impalpably fine material has been removed during wet-table treatment.

The action produced in the usual type of electrostatic separator consists in electrically giving the relatively conductive particles a horizontal component of motion in addition to the motion produced by gravity. The less conductive particles not being thus affected are acted upon by gravity alone. The heavier the conductive particle, the stronger must this repellant force act to cause it to fall on the outer side of the divider of the machine. The repellant force is dependent upon the intensity of the electrostatic field. As electrostatic separation treats particles varying greatly in size, therefore, with a field sufficiently strong to repel the very heavy particles, there is danger of the finer, less conductive particles being thrown over also. Hence it is advisable not to have a feed in which the particles are too widely diversant in size, and therefore in weight. In practice the feed is screened into a few sizes, of which screening the following is an example: from 8 to 12; from 12 to 20; from 20 to 50, and through 50-mesh. When the difference in conductivity of the minerals is small, it is sometimes advisable to size somewhat more closely.

Ores are often found which crushing to 10 mesh, for example, will expose practically all the mineral, but will free but little of it. Because of the numerous separation fields to which the material is subjected while passing through the separator, all sides of every particle are brought into contact with the charging surface, and nearly every particle which contains an appreciable portion of exposed mineral will be repelled, while practically all the barren rock will be left in this coarse condition. The mineral can all be thrown in a concentrate, or the better part into the concentrate from the first two or three rolls, and the balance into a middling for re-crushing.

The real difficulty in the introduction of electrostatic separation was the design of electrostatic separators which would not be influenced by the weather as frictional machines are. The complete solution of this important and difficult problem is the Huff machine, which is an electromagnetic generator, not a frictional machine. These generators work as independently of atmospheric conditions as does the ordinary lighting dynamo, and are capable of supplying any line or machine losses which may occur and yet hold the potential absolutely the same from day to day. Contrary to general belief, the difference of potential which is used in electrostatic separation is only from 18,000 to 25,000 volts, instead of the 100,000 volts or so earlier supposed to be necessary. There has been developed a small, compact 3-hp electrical set which is sufficiently large to care for the requirements of a 100-ton mill, and probably [illegible] plant. Protective devices [illegible]

the generators and the separators to prevent injury to workmen in case of accident at the separators and accidental contact with the high-potential line. In the four years of its field operation no one has been injured from this source.

As the effectiveness of any electrostatic separation depends on the differences in conductivity of the particles, it follows that there must be no extraneous factor interfering to affect the conductivity. Water is in the sense of electrostatic separation a good conductor. Therefore the particles must be dry. Some minerals dry very readily and remain so. Some are hygroscopic, and if allowed to stand cold for some time in a moist atmosphere, tend to collect on their surfaces an extremely thin film of moisture. However, experience has shown that by properly constructing the mill equipment so that the ore from the dryer passes immediately through its various paths, and is not permitted to lie for some time cold and exposed to the atmosphere of a room, very few minerals, and none of the common ones, offer any difficulty from this standpoint.

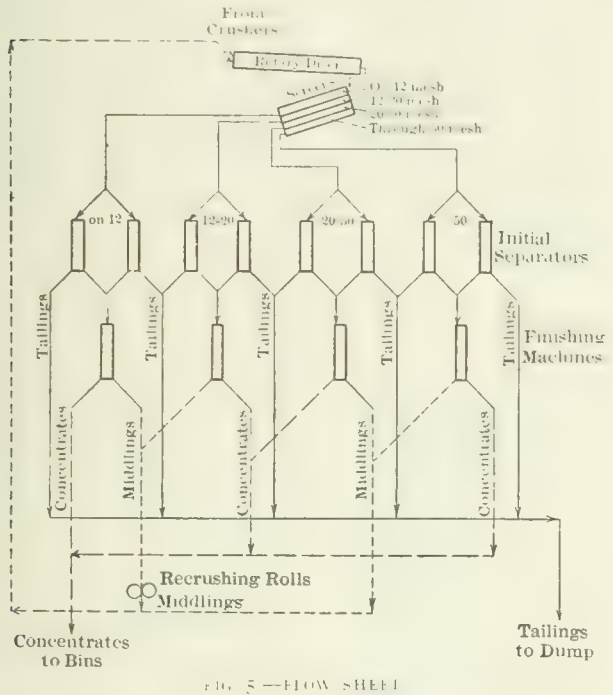

FIG. 5.—FLOW SHEET

There seems to be a very erroneous idea of the cost of drying ore. Crude mine ore will run from 1 per cent to 5 per cent of moisture; 3 per cent being a fair average. This means 60 lb. of water to be evaporated from each ton of ore. A fairly efficient dryer will expel from ore carrying 3 per cent moisture 5 lb. of water per pound of coal, or, say 12 lb. of coal to dry the ore. With coal at $5 per ton this means a fuel cost of $0.03 per ton. Fine middlings from water-tables will sometimes carry as high as 15 per cent of moisture, and the fuel cost is therefore increased under those circumstances to 10 cents or 11 cents per ton with the $5 fuel cost, as with the higher per cent moisture the evaporating power goes up to 8 lb. of water per pound of ore.

For electrostatic separation all the minerals may be divided quite closely into two classes: first, those which are very easily charged and repelled, and, second, the very poor conductors which act as non-conductors. A table of this kind was already given on page 296 of our Vol. VIII.

Most of the copper sulphide minerals are excellent conductors, while most gangue rocks are poor conductors. Therefore, electrostatic separation is applicable to the general concentration of the sulphide ores of copper. It is particularly well-adapted to the concentration of copper minerals from the heavier gangue minerals, such as garnet, epidote, barite, the heavy basic rocks, etc. Large bodies of ores of this character exist, often as altered contact-deposits, though, except in cases where the grade is sufficiently high for direct smelting, they have been developed but comparatively little, because difficulty has heretofore been found in concentrating them.

Often a combination of methods is more efficient than a single process, the governing factor being whether the size of operations warrants complexity of procedure. Very large copper mills employing gravity concentration produce a concentrate which has been carried to the economical limit of purification by the method employed, but which is yet capable of mechanical improvement if a different property of the ore than its specific gravity be worked on. Electrostatic separation offers a means of reducing the silica and other objectionable constituents of the gravity-mill concentrates.

Zinc blende usually occurs in mechanical association with pyrite or marcasite, chalcopyrite, galena and one or more gangue materials. The specific gravity of these minerals is approximately as follows: Galena, 7.5; pyrite, 5.0; marcasite, 4.8; chalcopyrite, 4.2; blende, 4; ordinary gangues, 2.7. From the smelters' standpoint, it is essential (for maximum recovery of the metal at minimum cost) that the material going into the lead smelter be as free from zinc as possible; that into the copper smelter free from zinc and lead, and that into the zinc smelter be as high in percentage of zinc as possible. Of the latter, theoretically 67 per cent is the maximum, but only in exceptional cases (as in the Joplin and Wisconsin districts) is 60 per cent zinc product obtained commercially by any method, while 50 per cent zinc is for most complex ores considered excellent and 45 per cent good.

With ores in which the various mineral ingredients dissociate at a reasonable (30 mesh or coarser) degree of crushing, gravity separators (jigs or water-tables) will usually effect a reasonably efficient separation of minerals which differ in specific gravity by 1.5 points, but as the difference in specific gravity becomes smaller the effectiveness of separation in the above manner becomes less, so that with a difference of but one point, the effectiveness of the separation is poor.

By putting such a complex ore, suitably crushed, through jigs and over reciprocating tables the galena (with a portion of the pyrite and marcasite) is efficiently concentrated from the rest of the minerals. Likewise the elimination of the gangue rocks is also reasonably well effected. There are left together a greater portion of the pyrite or marcasite, the blende and the chalcopyrite (with, of course, a little gangue and a small amount of galena). Fortunately the galena (which is usually so small in amount as to be negligible except for the associated silver which often occurs in it), the pyrite or marcasite, and the chalcopyrite are excellent conductors of electricity, while the blende and the small amount of gangue rock are very much poorer conductors. In the utilization of this difference of conductivity is seen the application of the electrostatic process to this problem. This mixture after drying (but not roasting) is passed through the Huff machines and two products made, one for the zinc smelter and one for the copper smelter.

Blende often occurs in association with certain heavy gangue rocks whose specific gravity is so similar to that of the blende that separation by any gravity means is very ineffective. A method has been developed by the Huff company whereby the surface of the blende can be made conducting, after which the blende can then be separated electrostatically from the associated rock minerals. Two important instances of the above are blende and barite, and blende and fluospar.

In addition to the concentration or separation of the sulphides mentioned heretofore, the Huff process has proved that it also accomplishes the following results very satisfactorily: concentration of gold and silver pyritic ores, of antimony, arsenic, and molybdenum sulphides; concentration of graphite, of pyrite for sulphuric acid manufacture, hematite, manganese ores; the separation of galena and barite; purification of abrasives, natural and artificial; and the solution of many problems relating to the more rare minerals. Copper oxides, carbonates

and silicates can sometimes be concentrated, by first roasting to the conductive oxide, or reducing to the metal.

The process is essentially a dry one, obviating the troubles due to drought or freezing. The finished products require no further drying treatment prior to shipment or smelting to decrease freight expenses or fuel costs. Loss in slimes is avoided as the dust may be collected and is available for use if desired. There are no shaking or vibrating parts to the machines with the attendant wear and repair on the mechanism. The attendance necessary, after primary adjustment, is small and ordinary

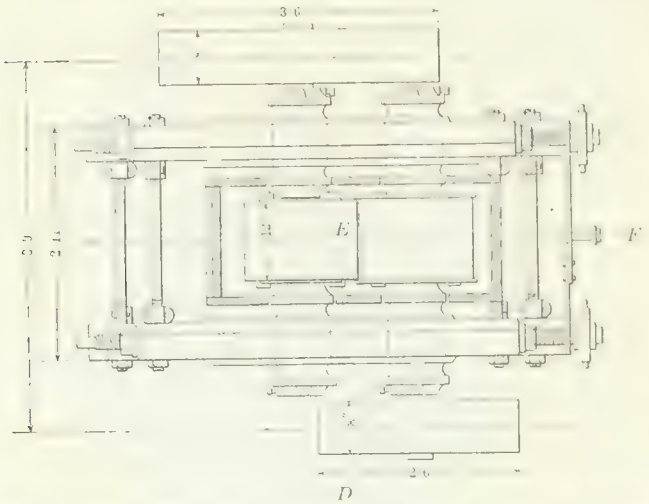

FIG. 6.—PLAN BELOW ROLL HOUSING OF FRAZEE CRUSHING ROLLS.

mill labor is suitable. The machines are readily sectionalized for light transportation and easily assembled. There are no complicated or intricate parts to get out of order and the separators are readily adjustable while operating.

In conclusion Mr. Wentworth pointed out that while drying is a requisite of electrostatic concentration, drying should not be confused with roasting. Not only is drying much cheaper, but roasting would have the great practical disadvantage that the particles would be liable to agglomerate and frit together and thus become unsuitable for electrostatic separation.

In the discussion which followed Prof. R. H. Richards remarked that electrostatic concentration, electromagnetic concentration, and flotation processes are a group of processes now coming to the front which do not depend on differences in specific gravity.

Roll Crushing.

The first paper of the Wednesday morning session dealt with "progress in roll-crushing," the author being Mr. C. Q. Payne.

Marked progress has been made within recent years in the field of coarse crushing by means of rolls, in response to the greater demands of modern mill practice, and this progress has been largely brought about by increasing the dimensions of the rolls and adopting a more massive construction, as well as a better design, combined with a wider choice of steel adapted to different ore requirements than has heretofore been available.

On the other hand, up to the present time rolls designed for fine crushing, where the ore requirements demand a maximum granulating effect and a minimum pulverizing or sliming effect upon the crushed product, have made little progress compared with rolls designed for coarse crushing. Mr. Payne points out that further advance in the art of fine granulation by means of rolls can only be expected by means of certain refinements of function whereby the roll-faces can be maintained parallel while they undergo wear.

These difficulties have been completely overcome, in Mr. Payne's opinion, in a recent design of rolls by Mr. J. S. Frazee, of Brooklyn, N. Y.

Figs. 6 and 7 show a pair of 18-in. × 12-in. rolls in plan and part sectional side elevation. The bearings of the roll shafts are supported in side frames. These are of cast iron, without tension rods, and are held together by stay-bolts and lock-nuts to permit the width between the frames to be slightly adjusted, if necessary, when the rolls are in place.

This construction has certain advantages for fine crushing over the single bed-plate or frame. It is lighter, less expensive, and permits the rolls to be completely boxed in by means of a wooden housing. This is hoppered at the bottom, and is connected with an exhaust-air pipe, through which the fine dust is drawn by means of a fan, thus keeping the mill space free from dust.

The bearings are of the solid type, lined with babbitt, and each provided with dust caps at each end. All four are movable in the guides provided for them in the frames. Two of the bearings are held against a spring pressure, and the other two against screw adjusting bolts, for the purpose of regulating and controlling the space between the roll faces.

These adjusting bolts are provided with sprocket wheels and an endless link chain, which is kept taut by means of a small idler between them. By inserting a long-handled spanner in openings in either of the sprocket wheels the adjusting screws can be moved in exact unison in varying the position of the roll space. This feature has been found a very con-

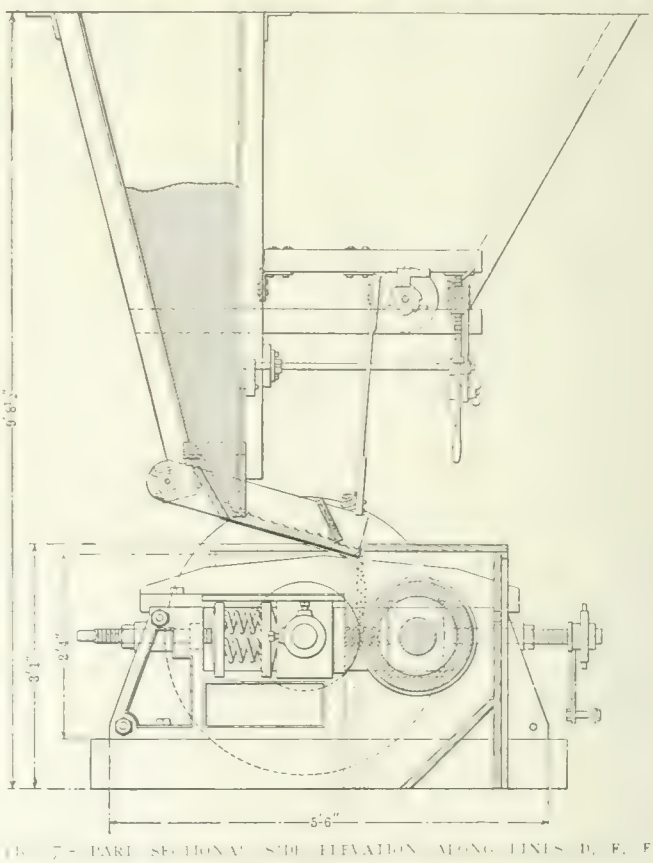

FIG. 7.—PART SECTIONAL SIDE ELEVATION ALONG LINES D, E, F OF FIG. 6.

the gap between the roll faces to be made while the rolls are running.

One of the essential features of Mr. Frazee's design consists, as shown in the illustrations, in making one roll-shell longer than the other, so as to permit flanges to form on it between which the shorter roll revolves with a slight clearance. The rolls are fed from a hopper, which is supported independently of the roll frame and in such a position as not to interfere with the removal of the rolls.

The lower end of the hopper is made of cast iron and is provided with a gate, which is operated by means of a shaft

and levers so that it can be controlled from the forward end of the roll frame. A feed tray is placed below the hopper so as to convey the material to be crushed from the hopper gate to the space between the rolls. This feed tray is supported at the back of the hopper by a pivot-bolt, which allows it to rotate slightly, and at the front end by means of a wooden connecting rod to a horizontal arm flexibly connected to a support at the front of the hopper.

When the front end of the arm is raised by the teeth of the revolving cam below it, the discharge end of the feed tray is caused to rise and fall with a jarring or bumping motion. This causes the material in the feed tray to be carried forward and to be discharged in a steady stream over the angle-iron which forms a lip or dam at the extreme edge of the tray. The bottom of the feed tray is made of sheet steel to permit the material to slide freely.

The amount of motion imparted to the end of the feed tray can be varied by means of an adjusting screw bolt, which regulates the height of the drop of the horizontal arm, and thereby also the effect of the bumping action upon the feed. A small lever at one side of the adjusting bolt permits the horizontal arm to be raised above the level of the cam, and in this way the feed can be instantly stopped and started.

It has been a common experience that as rolls are usually fed, even when great care is taken to secure a feed sheet of uniform thickness, the roll-shells will groove and wear more rapidly at their centers than at their ends. This is frequently caused by a difference in the rate of flow of the feed stream owing to friction of the sides of the chute or spout leading from the hopper to the rolls.

Another cause of greater wear of the central portion of the roll-shells is the greater mobility of the feed stream in certain directions than in others when subjected to a crushing pressure. This difference in mobility causes a difference in the amount of abrasion, and it shows itself by the cupping, grooving, or corrugating of the roll-faces along the center and by ridging at the edges of the roll-shell.

Mr. Frazee has found that the difficulty of irregular wear of the roll-shells can be entirely overcome by a close control over the sectional shape and area of the feed stream and by feeding a greater amount of material along the sides of the roll faces than at their centers.

The projecting side of the angle iron which forms the lip of the feed tray is cut down at its two ends so as to slope gradually towards the ends, leaving its full height only at the center. In this way the feed stream passing over the lip or dam is made thicker at the ends than at its center. Furthermore, to regulate the flow and upper contour of the feed stream, as well as the lower, a guide plate, which is usually hinged to the sides of the feed tray, is allowed to rest upon the surface of the feed-stream. This is provided with a wearing plate at its lower edge, and is so beveled at its two ends as to permit a somewhat greater freedom of flow of the feed-stream at its edges than at its center.

The cross-section of the feed-stream is adjusted to secure an equal abrading effect across the entire width of the roll faces, and thus to maintain them in perfect parallelism while they undergo wear. The exact cross-section of the feed-stream will vary somewhat with the hardness of the different materials to be crushed. This can be easily adjusted by varying the amount of bevel given to the edges of the angle iron and of the guide plate in the feed tray until the feed-stream exerts the desired uniform abrading action.

The flanges upon the longer roll-shell perform two functions. They not only confine the feed-stream at its end and prevent ridges from forming at the ends of the unflanged roll-shell, but by carrying the feed-stream a slight distance beyond the end of the shorter roll-shell, a small amount of crushing is performed between the sides of the flanges and the ends of the roll-shells. This flange crushing, being in opposite directions, balances, and all tendency to exert end thrust of the shafts against their bearings is in this manner neutralized and overcome.

By the simple means thus provided it becomes possible for the roll tender to maintain the roll-faces parallel while crushing even the hardest material, and to keep the rolls in continuous operation until the roll-shells are completely worn out. The only assistance required of a machinist is occasionally to turn off the edges of the flanges when they become so long that they strike the bolts of the opposite roll which hold its roll core in place.

This new roll design and manner of operating rolls has been developed by Mr. Frazee in connection with the dry crushing of very hard materials used for abrasives, such as quartz, garnet, etc. It is equally applicable to ores, and by the settling and removal of water from the mill feed it is possible to apply it to wet crushing as well as dry. The field which is thus opened up in connection with ores which require careful granulation, in order to prepare them for concentration, is a very large one. Mr. Payne thinks there is an especially large field for this new roll design in the treatment of complex ores, when very fine crushing without production of slimes is essential.

Mr. Payne's paper was briefly discussed by Mr. Spilsbury and Dr. R. H. Richards.

Electrolytic Copper Refining.

The first paper presented at the Wednesday afternoon session was of very pathetic interest, being the last contribution to metallurgical literature by the late Horace H. Emrich. As noted in our issue of November of last year, page 617, Mr. Emrich was killed on Oct. 17 at Kyshtim, Russia, where he was manager of the copper refinery; it is believed that his murderer was a discharged workman.

Early in 1911 Mr. Emrich had sent from Russia to his uncle, Mr. Karl Eilers, in New York the first part of his paper; the second and more important part was received by Mr. Eilers five days after receipt of the cable message of Mr. Emrich's death.

Mr. Emrich's paper was summed up by Dr. R. W. Raymond.

The first part of Mr. Emrich's paper dealt with the refining of copper in the reverberatory furnace for making anodes. It is shown that there is a limit beyond which it does not pay to go commercially in the refining process in the reverboratory furnace.

The second part deals with electrolytic copper refining and describes experiments which Mr. Emrich began when he was superintendent of the copper refinery of the American Smelting & Refining Company at Maurer, N. J. He wanted to find the reasons why bad cathodes are bad. His chief observation was that when he took a portion of a "bad cathode" *without re-melting it,* he could draw a wire from it that was very good and had 99.5 per cent electrical conductivity. Hence, the impurities which were in the cathode were not alloyed or chemically combined with the cathode copper, but were mechanically disseminated in it. It is only as a result of re-melting the cathode copper that the impurities become alloyed with the copper with the resultant decrease in electrical conductivity.

Now the question arises: If the impurities are simply mechanically embedded, are these impurities really precipitated at all from the electrolyte? For there is the alternate possibility that these impurities have their origin in the anode slimes and have been carried over mechanically from the anode to the cathode.

This latter view was indeed supported by the fact that an analysis of the impurities in the copper cathode and an analysis of the anode slimes showed that the proportion of arsenic to silver in both was the same.

Further, with a pure anode and a poor electrolyte a first-class cathode may be obtained because the pure anode produces no slimes.

As long as there are sufficient copper ions in the electrolyte arsenic will not be deposited on the cathode.

In the discussion Dr. Keith, Mr. Eilers, and Dr. Ledoux participated. Dr. Ledoux stated that in some cases poor results could be traced to carelessness in preparing the molds and in casting. He also told some rather peculiar cases of difficulties experienced in electrolytic copper refineries.

Decomposition Temperatures of Sulphates.

A paper by Prof. H. O. HOFMAN and Mr. W. WANJUKOW on "the decomposition of some metallic sulphates at an elevated temperature in a current of air" was presented by Professor Hofman.

The subject is of very great practical importance in the roasting of sulphide ores and there is a regretable lack of exact data. It is true, various investigators have worked on this subject, but their results are hardly comparable with each other on account of the differences in the arrangement of the experiments

Recently Professor Friedrich, in Breslau, has made a series of careful determinations, using a tube, one end of which was closed. Professor Hofman's arrangement differs from this in that he used a tube open at both ends. Hence there are differences between the results, Friedrich's temperatures being generally higher.

Professor Hofman used a tube open at both ends so as to have an open air current, so that SO_3 is withdrawn as soon as formed. This corresponds to actual practice conditions better than the use of a tube closed at one end.

The time required is quite different with the different materials, since some give up SO_3 readily, others do so slowly.

The determinations so far made by Professor Hofman are given in Table 1.

TABLE 1.

Sulphate	Decomposition Temperature Degree C.	Product.
$Fe SO_4$	150°	$Fe_2 O_3 (SO_4)$
$Fe_2 (SO_4)_3$	530	$Fe_2 O_3$
$Bi_2 (SO_4)_3$	540	$5 Bi_2 O_3 . 4 (SO_4)$
$Cu SO_4$	653°	$2 Cu O SO_3$
$Mn SO_4$	680°	$Mn_3 O_4$
$2 Cu O . SO_3$	704°	$Cu O$
$Ni SO_4$	708	$Ni O$
$Co SO_4$	718	$Co O$
$Zn SO_4$	739°	$Zn O$
$Cd SO_4$	830°	$5 Cd O . SO_3$
$5 Bi_2 O_3 . 4 (SO_4)$	850°	$Bi_2 O_3$
$5 Cd O SO_3$	875°	$Cd O$
$Ca SO_4$	1200°	$Ca O$
$Ba SO_4$	1580	$Ba O$

Still missing $Mg SO_4$, $Al_2 (SO_4)_3$, $Pb SO_4$, $Ag_2 So_4$.

Professor Hofman's paper was briefly discussed by Dr. Ledoux and Mr. W. A. McA. Johnson, who stated that for $ZnSO_4$ he had found a decomposition temperature very close to that of Professor Hofman.

Dust Precipitations by Electrostatic Means.

The last paper of the meeting, by no means the least in interest or importance, was presented by Dr. F. G. Cottrell of the Bureau of Mines, on his electrostatic process for the precipitation of suspended particles from gases and fumes.

Dr. Cottrell's extempore remarks on the work done by him in the past five years or so, while he was professor at the University of California, proved really fascinating. His address

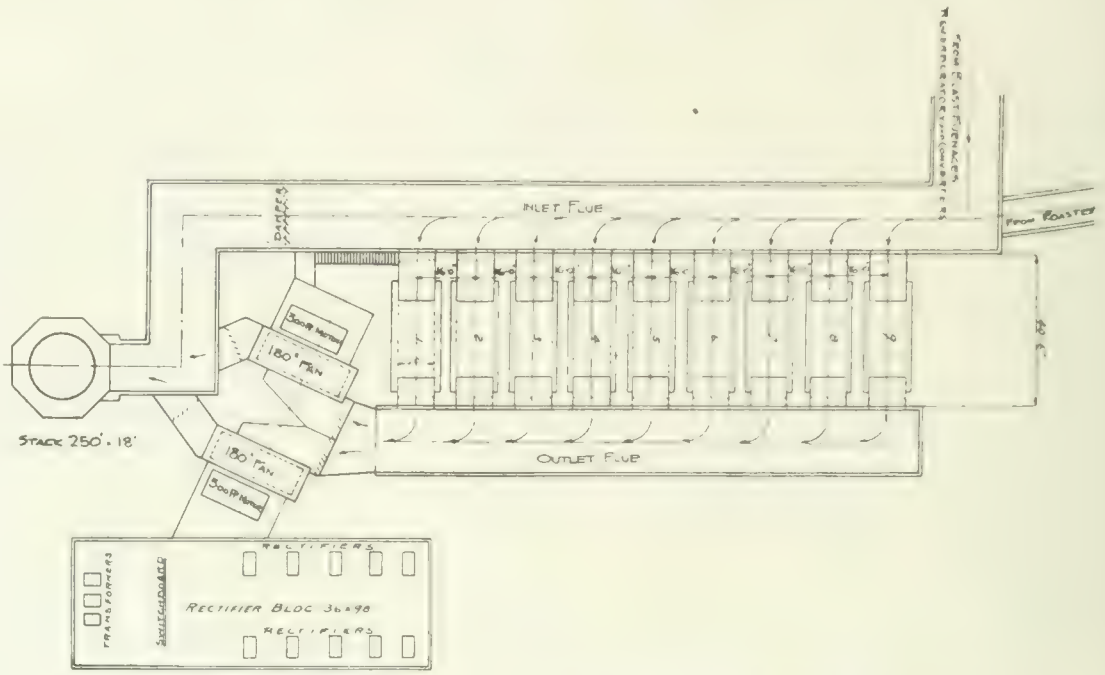

FIG. 8. GENERAL ARRANGEMENT OF PRECIPITATION PLANT AT BALAKALA SMELTER.

was brilliantly illustrated by many very instructive lantern slides

The fundamental principle of Dr. Cottrell's process is the same as that of Sir Oliver Lodge's early scientific pioneer work on the same subject. But Dr. Cottrell succeeded in reducing the scientific idea to successful engineering practice on a large scale.

The principle of Dr. Cottrell's process may be described by means of an old well-known experiment.

If a metallic needle point is placed opposite a flat metallic plate and the needle is connected to one pole and the plate to the other pole of a high-voltage direct-current supply line, electricity streams out of the needle point and charges the gas molecules in the space between needle and plate. The gas molecules thus receive an electric charge of the same sign as the needle point, hence opposite to the sign of the charge of the plate. They are, therefore, attracted by the plate and move toward the plate. This is the old, familiar phenomenon of the "electric wind" which may be illustrated by blowing out a candle flame brought into the space between needle point and plate.

Now if the space between needle point and flame is filled with a gas or fume in which particles of dust, etc., are suspended, these dust particles will be immediately charged with electricity and will, therefore, move toward the plate, stick to it and give up their charges. The speed of movement of the particles will be proportional to their charge and to the electrostatic field intensity (in volts per centimeter) in the space between point and plate.

This is concisely Dr. Cottrell's process. To make it suitable for working on a large scale, two fundamental problems had to be solved.

First, a practical, convenient, fool-proof method had to be evolved for the generation of a high-voltage direct current. (This is one of the differences from Lodge's work, who used the less effective alternating current.) Dr. Cottrell employs

ordinary commercial 20,000-volt to 30,000-volt alternating current and converts it into intermittent direct current by means of a specially designed rotary synchronous commutator. This intermittent direct current is directly used for charging the system of electrodes (needles and plates) in the flues which carry the gas under treatment.

The second important problem was to evolve a suitable mechanical construction of the electrode corresponding to the needle point in the above experiment. It is important to have as many and effective discharge points as possible. The solution of this problem was found in twisting asbestos filaments or mica scales with wires. The electricity passes from the wires by surface leakage over the asbestos or mica and the fine filaments of the asbestos or edges of the mica provide the required very fine discharge points, which are, indeed, far more effective than metallic discharge points.

As just explained this method presupposes that the electricity passes by surface leakage over the asbestos or mica surfaces. This surface leakage is made possible by the slight deposit of moisture or acid fume which naturally settles on the mica and asbestos surfaces. If the condition of the gases does not supply sufficiently such coating, the mica or asbestos receive a special treatment before being put into use.

The first lantern slides of Dr. Cottrell showed the arrangement of the original laboratory experiments in which the fumes of a little contact sulphuric acid plant were treated.

There was a big step from this small laboratory experiment to the large installation at the Balaklala copper smelter in Shasta County, California, shown in the next slides. This is one of the classical districts of injunctions of farmers against smelters.

The gases from the blast furnaces, roasters, etc., in the Balaklala smelter are passed into a common flue 18 ft. x 20 ft. in cross-section. The volume of gases passing through this flue vary with operating conditions for 250,000 cu. ft. to 500,000 cu. ft. a minute, the mean velocity of the fumes in the flue being between 10 ft. and 20 ft. per second.

Fig. 8 gives a plan of the nine Cottrell precipitation chambers in their relation to the flue system. Three-phase currents at 2300 volts are transformed up to 25,000 or 30,000 volts and then rectified into intermittent direct current, as noted above, and distributed to the various Cottrell precipitation chambers.

Fig. 9 is a cross-section through one of the Cottrell precipitation chambers. The double vertical lines represent the collecting or grounded plate electrodes, each 6 in. wide by 10 ft high, made of No. 10 sheet iron.

The dotted lines represent the discharge electrodes consisting of two iron wire strands between which are twisted the asbestos and mica flakes which provide the discharge points. Each chamber contains twenty-four rows of twenty-four electrodes.

Whenever sufficient dust has accumulated on the plate electrodes, the current is cut off and the plate electrodes are shaken free from the dust, which falls down and is carried by the conveyor in each unit to a common longitudinal conveyor.

The installation is not in operation now, since by court decree the Balaklala smelter was shut down until it can live up to the letter of the original degree, viz., remove *all* solids, never exceed 0.75 per cent sulphur dioxide, and *do no damage*. The chief difficulty is in the sulphur dioxide. That the Cottrell system is successful for settling the suspended dust particles was completely proved.

Another more recent application of the Cottrell process is the settling of dust from Portland cement kiln gases, which is now in successful use at Riverside, in southern California. Since the orange groves in that district are exceedingly valuable, the prevention of dust from the cement works (which are ideally located there in every other respect) was very important. This problem has been successfully solved by the installation of the Cottrell system at the Riverside Portland Cement Works. This was shown in various lantern slides.

One amusing feature of this installation is the recovery of potash from the settled dust, so that the farmers who were responsible for the installation will also enjoy this by-product profit.

Another recent development is an experimental plant for the treatment of copper converter gases for the recovery of lead. An interesting new feature of this plant is that no flat plates are used for the settling of the dust, but round pipes with the discharge wires in the center.

Some of the lantern slides shown by Dr. Cottrell were striking in showing the smoke coming from the smokestack. This was always shown by two photographs side by side; the first was taken while the electric current was switched off and showed a big black volume of smoke; the second photograph was taken a few seconds later after the current had been switched on and showed an absolute absence of black smoke, thus proving the almost instantaneous effectiveness of the electric process.

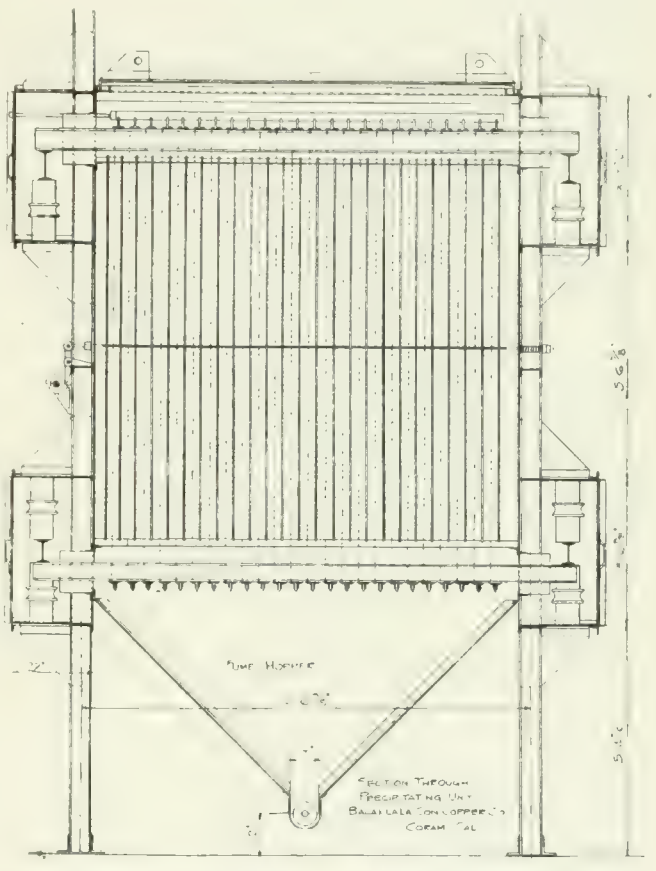

FIG. 9.—CROSS-SECTION THROUGH ONE OF THE ELECTROSTATIC PRECIPITATION CHAMBERS.

Dr. Cottrell finally referred briefly to his signing over his patent rights to the Smithsonian Institute, which will form a subsidiary corporation, the proceeds from the process to be used for the encouragement and aid of research. Considerable interest is being shown in this idealistic development not only in this country, but abroad. When the formation of the subsidiary corporation will be effected, we will cover this non-metallurgical, yet very inspiring feature of Dr. Cottrell's work in greater detail.

In the discussion which followed, Dr. Cottrell stated that the shaking off of the dust from the plates offered no difficulty whatever in practice. Simple rattling is sufficient.

As to the cost, the first cost of the installation of the Balaklala smelter, which can treat 500,000 cu. ft. of gas a minute, was about $135,000 until the construction was finished.

The first cost of the installation of the cement plant, which has about the same capacity, was less, being about $100,000.

With the more recent pipe construction adopted for the treatment of converter gases, as mentioned above, the first cost may be very materially reduced.

The cost of operation is very small. The power cost is almost insignificant. At the Balaklala smelter it was 120 kw. At the Riverside cement plant, which turns out 400 bbl. a day, it is 50 kw for the whole plant, which is negligible compared with the other power requirements of the plant.

Mining and Geological Papers.

In the Wednesday morning session Mr. S. A. KROM presented a paper on the James diagonal slimes concentrating table. It is the invention of Mr. U. S. James, of Newark, N. J., and its first installation is at the Hudson Bay Mine, in Cobalt, Ont., Canada. Since the paper was not printed in advance and the construction of the table cannot be understood without the aid of diagrams, we defer a description of the James table for a later occasion.

The following papers on mining and geological subjects were also presented and discussed at the meeting:

Prof. James F. Kemp on the Gold Hill Mining District in Western Utah.

Prof. Charles P. Berkey on the Geology of the New Catskill Aqueduct (giving some most interesting details on the geology of New York City).

Dr. F. F. Hahn on the Geology of the Salt Deposits of Western Germany.

Prof. C. A. Stewart on the Geology and Ore Deposits of the Silverbell Mining District.

Prof. Alfred C. Lane on Stagnant Mine Waters.

Mr. N. H. Emmons on A Concise Method of Showing Ore Reserves. This paper elicited quite an extended discussion as to the limits within which the proposed method may be applied in practice.

There was also on exhibition a new and very convenient electric miners' lamp made by the General Electric Company.

Before the meeting adjourned the thanks of the Institute were voted to the retiring president, Mr. Charles Kirchhoff, for all the successful work done by him during his administration.

Notes on Chemistry and Metallurgy in Great Britain.

(From our London Correspondent.)

The Standardization of Electrical Machinery.

At the meeting of the Institute of Electrical Engineers held early in December a paper was read by Dr. Robert Pohl entitled "Notes on National and International Standards for Electrical Machinery." The author reviewed the issues of the British Engineering Standards, and said the desired revision had possibly been delayed for the outcome of the deliberations of the International Electrotechnical Commission, the president of which took the hopeful view that "in many particulars the countries were already in such substantial agreement that the anticipated difficulties were much less than might at first appear." After dealing with the scope of standardization the author remarked that the points of any standard specification which were perhaps the most important, viz., those dealing with working qualities, had only been touched upon by the existing standards in regard to rise of temperature, and sparklessness, overload capacity, voltage regulation, efficiency and power-factor, and insulation all required consideration.

In the discussion, Mr. T. Hording Churton said the variety of frequencies and voltages in use presented serious difficulties to general standardization. There was, however, scope for framing rules to be generally recognized for the rating and testing of machines in which there was at present great diversity of opinion and practice.

Mr. W. E. Robson considered that the regulations of the Standards Committee were ineffectual. One of the main objects to be attained was the improvement of the standard of performance, but it would first be requisite to ensure the observation of the standards by all manufacturers. The sale in England of foreign-made machines which did not conform to such standards should be made an offence, but there was little hope of this being done while the open-market policy was maintained.

Mr. Robert Hammond said the object of the Standards Committee had been to secure efficiency with reduced cost of production, and their previous conclusions had not been of a haphazard nature. Many of the tests advocated by the author had actually been carried out on their recommendation. The committee selected the sizes of machines which most makers regularly produced and which therefore involved no extra outlay, but they also had to make the conditions of tests such as would keep the consulting engineer in check. There was one thing in the standard specifications he wished Dr. Pohl would acknowledge—that the committee had swept away the overload absurdity; for it was absurd to specify a certain rise of temperature for a machine with a given load and then require it to stand 25 per cent more.

Prof. Silvanus P. Thompson was of opinion that a six-hours' or other long run was unnecessary to ascertain the output and temperature rise. The temperature curve was quite regular, and the final figure could be easily calculated from the result of a shorter run.

Mr. H. Jones said that foreign competition did not affect British firms in regard to small standard machines, but was felt in schemes entailing the use of large machinery.

Dr. Pohl, in his reply, said he would like the standards to be reconsidered by a committee constituted similarly to that which drew up the previous specifications. He desired to shorten the duration of tests. He could not agree that overload had been swept away by the committee. The variation existing in this country in frequencies and voltages was no argument against an effort to achieve standardization. Manufacturing costs were too high in this country in this particular industry, and efforts for their reduction should be made in the direction of organization.

Corrosion Research.

The plant furnished by the Corrosion Committee of the Institute of Metals at the metallurgical department of the University of Liverpool for the study of the corrosion of non-ferrous metals was formally inaugurated in the middle of December by Sir George Muntz, who congratulated the university on conducting so important a research which had a particular interest for large seaports like Liverpool, and which had hitherto been much neglected by reason of its cost and the want of facilities for the work.

The investigation has for its especial object the observation of corrosion in brass marine condenser tubes, and will be under the direction of Mr. G. D. Bengough, the university lecturer in metallurgy.

The nature of the experiments and the proposed methods of carrying them out were laid down by the corrosion committee some months ago, and did not meet with a full measure of approval with some metallurgists and others whose opinions are entitled to consideration. It is therefore to be hoped that modifications of the original scheme have been or will be effected.

Estimation of Free Sulphur in Spent Oxide.

Before the London section of the Society of Chemical Industry, Messrs. C. DAVIS and J. L. FOUCAR recently described a quick and fairly accurate method of volumetrically determining the sulphur in spent oxide, particularly such as contains small amounts of organic matter soluble in the solvents usually employed for the extraction process, which necessarily gives results higher than the truth, while the oxidation method is prolonged and requires careful manipulation. The new method

consists in digesting the finely pulverized oxide, after drying, with sodic cyanide solution in absolute alcohol, filtering, and titrating the sulphocyanide. The results do not vary widely from those obtained by oxidation, and are accurate enough for all commercial purposes.

Engineering Imports and Exports.

The returns issued by the Board of Trade for the year 1911, put the value of imports of iron and steel, including manufactures, at £11,144,211, an increase of £2,057,997 on the year 1910, and exports at £43,751,618, an increase of £774,947. Imports of other metals including manufactures, reached £27,592,-152, showing a rise of £2,892,058, and exports £11,027,269, also a rise of £$674,915. Imports of electrical goods totalled only £1,435,429, a decline of £251,111, and exports were £2,824,271, a loss of £1,278,331. Imports of machinery went up to £5,679,-274, increasing by £1,298,376, and exports to £30,977,403, an increase of £1,706,023. Imports of new ships are valued at £64,-484, an advance of £37,380, while exports were £5,662,045, dropping £3,108,159.

Taking the month of December alone, imports increased were iron and steel, £40,209; machinery, £57,362; and the decreases were other metals, £33,271; electrical goods, £60,806; ships, £916. Exports increases: Iron and steel, £111,951; other metals, £78,751; machinery, £87,850; ships, £645,538. Exports decrease: electrical goods, by £388,059.

Market Prices.

January, 1912.

Copper has not been so steady as appeared probable. Starting at £63 it rose by the 8th to £64⅛ and then fell (15th) to £60¾, rising again to £62 (19th) it has since declined and closes £61.5s.0d. At present the fall in price of this metal is a leading feature in the metal market.

Tin dropped sharply from opening price of £200 to £190 on the 3d, recovered to £193 by the 5th, and then fell to £183 (12th), since rising to £191 (18th) and closing at £194.

Lead has been fairly steady with slight weakening 12th to 19th. Opened at £15, closes at £15-17-6.

Haematite has been uneven. Opened at 64/9, fell to 62/10 by the 11th, recovered to 63/6 by the 17th, and closes at 63/6.

Scotch Pig opened 55/4, fell to 54/2 by the 10th, and remained below 55/-, closing at 54/9.

Cleveland followed the same course as Scotch Pig, opening at 49/3 and closing at 48/9.

India-rubber has not presented any remarkable features during the month. Opening at 4/3½ it closes at 4/8.

Synopsis of Metallurgical and Chemical Literature.

Iron and Steel.

Reduction of Iron Oxides in the Blast Furnace, Open Hearth, and Graphite Crucible.—In *Stahl und Eisen*, 1911, November 2, page 1808, a brief abstract is given of a paper by the Russian author, B. POMERANZEFF, who has come to some conclusions on this subject quite different from the views ordinarily accepted.

1. The reaction common assumed to be

$$FeO + CO = CO_2 + Fe$$

is considered not to be correct. It should be replaced by the following equation:

$$3\,FeO + CO + C = 2\,CO_2 + 3\,Fe$$

2. Reduction by means of elemental carbon (uncombined) in a blast furnace, open hearth, or graphite crucible does not occur.

3. For the reactions or processes which occur in a blast furnace the following equations are given:

$$Fe_2O_3 + CO = CO_2 + FeO$$
$$3FeO + CO + C = 2\,CO_2 + 3\,FeO$$
$$3\,FeO + CO + 2C = 2\,CO_2 + Fe_3C$$
$$Fe_3C + FeO\,CaO\,SiO_2 = 4\,Fe + CO + CaO\,SiO_2$$
$$3\,Fe_3C + MnO\,SiO_2 = 9\,Fe + Mn + Si + 3CO$$

No explanation of these equations is given in the German abstract, the original paper having appeared in the *Journal of the Russian Met. Soc.*, 1911, Vol. 4, p. 366/75.

Smelting and Reduction of Titaniferous Iron Ores in Electric Furnaces.—Prof. W. BORCHERS discusses in *Stahl und Eisen*, May 4, 1911, page 1706, the various investigations carried out on this subject in his laboratory at Aachen. When an oxide ore is smelted two layers must be usually distinguished, the lower layer consisting of the heavier oxides and the upper layer being the slag which results from the gangue. If for some reason this process has to be conducted in an electric furnace and the oxide is to be reduced to metal by means of coke, charcoal, etc., an undesirable phenomenon is liable to happen. Before the reducing agent becomes effective the heavy oxide may separate from the mixture and accumulate on the bottom of the furnace (perhaps with some reduced metal below), while the reducing agent is separated from the oxide by the liquid slag. (This being called a case of "liquid concentration.") Nor does occasional agitation prove a remedy. Briquetting of ore and coal previous to the smelting process would result in an increase of cost and require separate apparatus.

In Borchers' laboratory tests for smelting titaniferous ores have been conducted for about twelve years for the purpose of reducing the iron and recovering the titanium in form of a useful product. Huppertz worked along these lines in 1904 on the reduction of titanic acid and compounds. Further Lugner (1898-99) and Huppertz (1904) showed that the reduction of titaniferous ores in an electric furnace offers no

special difficulties, iron with small percentage of titanium being reduced, while most of the titanium is concentrated in the slag. It was shown that, in the absence of nitrogen and at temperatures of below 2000° C., only a very small amount of titanium is reduced into the iron. The blast furnace where such temperatures prevail is, however, not a very successful instrument for this process owing to the formation of nitrides and cyanides of titanium and iron on account of the great quantities of nitrogen present in the air of the blast.

The first tests by Borchers on melting a mixture of titaniferous ores with reducing agents did not turn out very satisfactory owing to the phenomenon of "liquid concentration" mentioned above. The power consumption per unit of output was exceedingly high, while even agitating would not bring the molten ore in contact with the carbon. Another remedy had to be looked for and was found in the following fact:

If titaniferous ore is smelted with an insufficient amount of carbon in order to reduce iron oxide a part of the iron oxide will be consumed for the formation of slag with titanic acid. With just the right amount of coal, a fairly liquid, highly titaniferous acid slag is obtained, its composition being within the limits: 40-47 per cent TiO_2, 20-5 per cent SiO_2, 34-30 per cent FeO. This titanate, as it may be called, may be used as the raw material for the production of titanium alloys. When reduced by carbon a mixture of iron-titanide, titanium carbide, and metallic titanium is obtained with free carbon according to the amount of carbon used, and consisting approximately of 42-48 per cent Ti, 5-1 per cent Si, 20-6 per cent C, 30-8 per cent Fe. This mixture of titanides and carbides is a very good reducing agent; moreover, it is heavy enough to come in direct contact with the molten ore. In other words, the reducing carbon is burdened with iron, titanium, and silicon, to produce a very efficient reducing agent, by which means the time for the main reaction between ore and reducing agent is considerably reduced while the power consumption becomes a minimum.

A scheme for a large plant using this process might be as follows: For the production of 1000 kg of iron two furnaces are to be used simultaneously.

Furnace 1—Electric resistance furnace: 400-450 kg carbon: 1000-1100 kg slag of above composition.

Furnace 2—Gas or electric furnace. 1600-1700 kg titaniferous ore containing 50 per cent Fe, 10-15 per cent TiO_2.

The molten material from furnace 2 is poured into furnace 1. Furnace 2 may be constructed larger than furnace 1, so that only part of its contents has to be added into one or more furnaces of type 1. It would hardly be preferable to reverse this practice, since the material in furnace 1 will not be melted and it is better to keep it at a very high temperature. The reaction in furnace 1 after addition from furnace 2 will not require any power consumption in larger furnaces and will give as product about 1000 kg iron and 1500 kg slag.

From this slag 1000-1100 kg are returned to furnace group 1 together with carbon; the rest of 400 kg is available for production of alloys of titanium. The flue gases of furnace 2, if operated by gas, may be utilized again in some way.

Nissen Stamps on the Rand.—At the City Deep mill on the Rand a comparative test between Nissen single-mortar stamps and ordinary stamps has been in progress. In the *Journal* of the Chemical, Metallurgical & Mining Society, of South Africa, for Oct. 1911, Mr. PETER N. NISSEN describes the advantages of the Nissen stamp and gives comparative results of the test mentioned. The Nissen stamp is of the heavy type, having been used as heavy as 2250 lb. It has a single mortar with circular screen, and larger diameter of shoes and dies than is common in heavy stamps, viz., 10 in. For the same tonnage the Nissen stamp requires about 30 per cent less power than ordinary stamps, and 40 per cent less weight of iron and steel in the battery. The accompanying tables embody the essential features of the test.

Continuous Decantation Accessory to Vacuum Filtration.—The use of Dorr thickeners in continuous decantation schemes has been suggested frequently. In the *Informes y Memorias* of the Mexican Institute of Mining and Metallurgy, Vol. 2, No. 5, J. LESLIE MENNELL suggests their use in connection with vacuum filters, as a means of removing a large portion of the soluble precious metals from the pulp before sending it to the filters. He has been working on specially slimy ores which do not readily yield to vacuum filtration, and has been bothered by excessive losses of soluble silver in the filter cakes. To give a concrete example: The soluble value left in cakes formed from pulp in which the solution carried 200 grams

silver per ton, has been about 30 grams silver per ton of cake, despite a wash of barren solution for 45 minutes and water for 10 minutes.

He proposes a scheme whereby Dorr thickeners installed ahead of the vacuum filter shall remove the greater part of his rich solution by decantation, so that the pulp finally going to the filter shall be comparatively poor, and the loss in the cake correspondingly low. The ore is crushed and ground in cyanid solution, agitated in Pachuca tanks at a consistency of 1.5:1, and sent to a thinning tank where mill solution is added, giving a consistentcy of 6:1. The solution now carries only 76.5 grams silver per ton as compared with 162 grams as it came from the Pachucas. It is now thickened in a Dorr machine and rich solution drawn off carrying 68.5% of the silver. This is the only solution that is precipitated, and effects the immediate removal of 68.5% of the value. The thick pulp issuing from the Dorr is again thinned with barren solution, and thickened in a second Dorr, whereby additional silver recovery is effected, bringing the total removal up to 94%. The thick pulp from the second Dorr is now sent to the Butters filter, carrying only 6% of the original silver value. Here it is filtered and washed as effectively as possible. Granting only a 50% displacement, there is recovered an additional 4.5% silver, making a total of 98.5%. The cake discharged will contain but 3.6 grams silver per ton of dry ore, instead of 30 grams as by direct filtration.

Recent Metallurgical Patents.

Gold and Silver.

Reduction of Arsenical Silver Ores.—The silver ores occurring in the Cobalt district, Canada, have been the subject of much experimenting to find suitable methods of recovering the cobalt, nickel and arsenic which they contain in appreciable quantities. Mr. COLIN G. FINK, of Schenectady, N. Y., has recently patented a combination process of treating these ores, which he assigned to the General Electric Company. A typical example is as follows: The ore contains, 9.7 per cent cobalt, 4.65 per cent nickel, 28.65 per cent arsenic, 18.06 per cent silver, with the balance of 39 per cent composed of iron, aluminium, calcium, silicon, antimony and perhaps other elements. The ore is ground to 40-mesh size, fluxed in a suitable manner to reduce the metals and form a slag of the gangue, and charged into a crucible or furnace where it can be heated under reduced pressure, as in the Arsem furnace (patent 785,535, 1905) The temperature is raised to 1200-1500 deg. C., and maintained for two or three hours. By this treatment the greater part of the arsenic is volatilized and condensed as metallic arsenic, and the charge in the crucible separates into strata of metallic silver, speiss of cobalt and nickel, and slag in the order named, silver being the lowermost. The charge can be allowed to cool and the separation of the strata made mechanically, or the silver can be tapped and purified by distillation in an Arsem furnace. The speiss also can be separated and treated in known manner for recovery of the cobalt and nickel. (1,013,931, Jan. 9, 1912.)

Imlay Apparatus for Cyanidation.—Claims of economy in cost of plant and operation are made for certain apparatus recently patented by WILLIAM L. IMLAY, of Philadelphia, Pa. By his method, the ore is not classified into sand and slime until after lixiviation in his machine. The apparatus consists of a slowly rotating cylinder, at one end of which the ore pulp in cyanide solution is fed, being discharged at the other end. The cylinder is lined with a helical flange and ribs which act as buckets. The cylinder is about 50 ft. long and makes 1 to 5 r.p.m. As it revolves the ore is slowly conveyed from one end to the other by the helical flange, and is continuously raised by the ribs and allowed to fall back into the mass of the charge. It is the inventor's claim that this agitation and aeration are most effective, and that a saving is effected in cost of plant and operation. (1,014,224, Jan. 9, 1912.)

Agitator and Classifier.—In Fig. 1 is illustrated a combination agitator and classifier with filter-bottom, which is the invention of J. W. FAIRFIELD, of Goldfield, Nevada. The inventor states that it may be used for the regular treatment of ore, but that it embodies features which make it specially

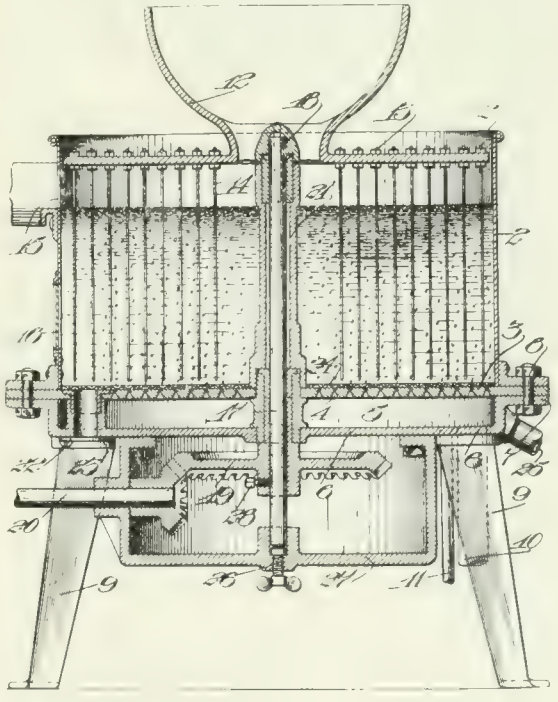

FIG. 1.—AGITATOR AND CLASSIFIER.

adapted to experimenal testing of ores by the cyanide process. It consists of a cylindrical tank 2, perforated false bottom 3, chamber 5, driving gear as shown, and feed hopper 12 to which are attached stirrers 14. An overflow spout for slime is provided at 15, and a gate for discharge of sand at 22. Water-pipe connection with the chamber 5 is shown at 10, and a similar air-pipe connection at 11. The pulp in cyanide solution is fed at the hopper 12, and falls into the tank where it is

agitated by the stirrers 14 attached to the turn table 13. Further agitation is effected by forcing water or solution or air through the chamber 5 and false bottom 3. The process may be continuous or intermittent, slime being discharged at 15 and sand at 22. In making tests on small lots of ore, the false bottom may be covered with a filtering medium, and after agitation and aeration have proceeded for a sufficient length of time, the solution may be filtered from the solid portion by applying suction at the pipe 11. (U.S.10,244, Nov. 28, 1911.)

Copper.

Bradley Process for Low Grade Ores.—Considerable interest attaches to the Bradley process because it is being tested experimentally on the slime residue at the Anaconda Copper Mining Company's concentrator at Anaconda, Mont. The method is the invention of CHARLES S. BRADLEY, of New York City, and is designed to handle successfully those low grade copper ores in which a small percentage of copper must be separated from a large percentage of gangue. The Anaconda slimes carry about 2.5 per cent copper, and are therefore comparable to the porphyry ores as regards copper content, although in physical condition they are much finer and more difficult to treat by physical methods. A diagram of the Bradley chemical process is given in Fig. 2.

The chemical principles involved in the process are as follows: Calcium chloride is used as a solvent and chlorine carrier, converting copper sulphate into copper chloride, and precipitating calcium chloride. The chlorine compound thus has the advantage of forming an insoluble compound in the reaction, and may be removed. The copper chloride solution may be precipitated by the addition of calcium carbonate, whereby calcium chloride is regenerated and copper oxide precipitated with evolution of CO_2 if the temperature is high enough. It will be apparent that the reaction of calcium chloride on the copper compounds requires the presence of an acid radical, and that sulphuric acid might be used as an added reagent to bring about this effect. But the inventor prefers to produce this acid radical from the ore by first roasting it to sulphate, thereby avoiding the expense of separate addition of acid. To operate the process it is only necessary to bring in a small quantity of calcium chloride to start the reactions and make up the waste as chlorine is retained in solution, and regenerate the calcium chloride when the copper value is precipitated.

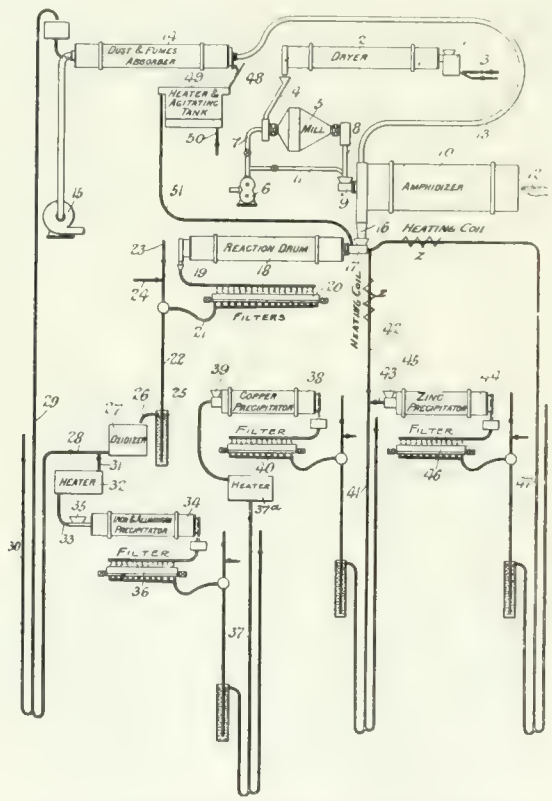

FIG. 2.—BRADLEY PROCESS FOR LOW GRADE ORES.

The inventor makes use of the term amphidizing to indicate the process of roasting copper sulphide to sulphate, and speaks of the roasting apparatus as an amphidizer. Amphide was a term used by Berzelius to distinguish those salts containing oxygen from the corresponding unoxidized salts.

The description of the process will be understood by reference to the figure. The first step is to crush and dry the material to be treated. It is then heated to a temperature of from 450 to 550 deg. C. with access of air, in the amphidizer where the sulphide of copper is largely converted into sulphate. In practice most of the iron in the ore will be converted into ferric oxide which is insoluble; but some iron will form ferric sulphate, and some of the copper will remain as sulphide, while other small portions will form copper oxide or remain as metallic copper if such was in the ore. The amphidizing apparatus does not require strict supervision as provision is made later for the treatment of any copper which shall not have been converted into sulphate, and of iron which has been formed into sulphate.

The dust and fumes which are formed in the amphidizer are collected in an absorber and made to serve a useful purpose, as will be shown.

From the apmhidizer the roasted ore passes to the reaction drum, which is rotatable and supplied with a solution of calcium chloride preferably at a little below boiling temperature. The ferric sulphate which may have been formed in the amphidizer here reacts with calcium chloride, forming ferric chloride and calcium sulphate. The ferric chloride thus formed serves to dissolve the copper oxide, sulphide and metallic copper remnants which were not oxidized in the amphidizer. Here also any sulphuric acid which may have been formed in the absorber, combines with calcium chloride to liberate hydrochloric acid which, in turn may also dissolve any unoxidized copper compounds, converting them into chlorides. The net result is that all the copper is converted into chloride, while the calcium is precipitated as sulphate. It is essential that an excess of calcium chloride be present, and that all the solutions be kept at their highest state of valency.

The pulp is now ready for filtration, and is discharged to the filters from which the calcium sulphate and gangue are eventually removed. The solution is then preferably subjected to further oxidation, as by blowing air through it, when it is ready for the precipitation and separation of the various metallic contents. It may contain iron and aluminium, as well as zinc, if such were in the ore. Calcium carbonate may be employed as the cheapest efficient substance, but inasmuch as it will precipitate iron and aluminium, as well as copper, and as copper oxide will react with iron and aluminium compounds as soon as formed, the former must be completely precipitated before the latter can remain as a precipitate and be recovered. On the other hand the iron and aluminium are useful in the absorption of the fumes, so only a part of the solution is subjected to precipitation and the other part is diverted to the absorber.

The precipitation of iron and aluminium is accomplished at the point designated in the diagram, and any copper which precipitates with them may be recovered by returning the precipitate to the amphidizer. Following the separation of the iron and aluminium, the copper is precipitated by calcium carbonate, thereby regenerating calcium chloride which is separated by filtration from the copper precipitate. If the solution contains zinc worth recovering this may be accomplished by precipitation with burnt lime. The solutions are heated prior to precipitation as indicated in the diagram. The regenerated solution is now returned to the reaction drum.

That portion of the original solution which was diverted t

the absorber reacts with the dust and fumes which have been collected, thereby recovering the values which might otherwise be lost. The sulphuric acid there formed from the SO_3 gas precipitates some calcium sulphate and liberates hydrochloric acid which, in turn oxidizes cuprous chloride which has been formed by the reaction of SO_2 and cupric chloride.

It will be noted in this system that the calcium chloride acts both as a solvent and as a carrier, circulating through the system from beginning to end, and when regenerated is restored without change of state. The chloridizing takes place in the drum and not in the roaster, and there is no tendency to overload the system with soluble chlorine salts which are difficult and expensive to remove. (1,011,562, Dec. 12, 1911.)

MacKay Copper Process.—Another proposal to make use of a metallic chloride as a solvent for copper in ores is that of HENRY S. MACKAY, of Riverside, Cal. He proposes to use ferric chloride which he prepares as follows: Sodium chloride is electrolyzed with iron anodes, producing ferric chloride and chlorine. This solution is added to the ore and the entire pulp subjected to air agitation. His claim is that the copper will be dissolved and the ferric chloride reduced to ferrous chloride. Then upon electrolyzing the filtered solution, the copper will be deposited and the solution of ferric chloride and chlorine regenerated. (1,011,459, Dec. 12, 1911.)

Electrolytic Extraction of Copper from Ores.—The rather peculiar use of chromic acid as a copper solvent is the basis of a patent granted to HENRY K. HESS, of Philadelphia, Pa. He proposes to treat copper ore suitably placed in a tank, using an electrolyte of sulphuric and chromic acids, and carry on solution and deposition at the same time. The ore is placed between electrodes, on one of which the copper dissolved by the chromic solution is deposited electrolytically. (1,014,061, Jan. 9, 1912.)

Still another proposal in the hydrometallurgy of copper is that of ANTONY GADOMSKY, of Tiflis, Russia. Calcined copper ore or uncalcined copper slags are ground and treated in a closed tank with a mixture of two solutions containing respectively 4 per cent ammonia and 4 per cent ammonium carbonate. The net result of the reaction is the formation of copper ammonium hydrate which readily dissolves in the ammonia. As soon as the solution is saturated with copper it is withdrawn to a still where the ammonia and CO_2 are driven off and dissolved in water for further use as a solvent of copper. Copper oxide is precipitated in this distilling process, and can be removed and reduced to copper by smelting. (1,014,868 Jan. 16, 1912.)

Zinc.

The Saeger Muffle Charging and Cleaning Machine.—In the illustration Fig. 3, is shown one design of the Saeger mechanical device for charging and cleaning zinc retorts. It

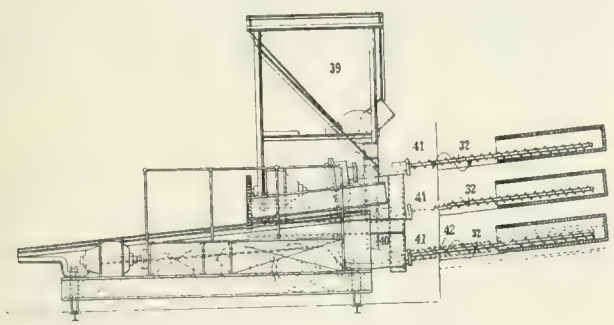

FIG. 3.—MACHINE FOR CHARGING ZINC RETORTS.

is the invention of OTTO SAEGER, of Breslau, Germany. Screw conveyers are mounted on a truck which can be moved along the front of a bank of retorts, and also in the longitudinal direction of the retorts. For this purpose a lower truck runs on tracks laid parallel with the front of the furnace, and an upper truck moves on inclined tracks laid at right angles to the front of the furnace. A charge hopper 39 is provided from which ore is fed by a distributing pipe 40 to short pipes 41 from the screw conveyers issue. In charging the retorts the screws have one direction of rotation, and in cleaning they have the reverse direction. In order that the ends of the retorts may not be damaged by reason of one screw reaching the end

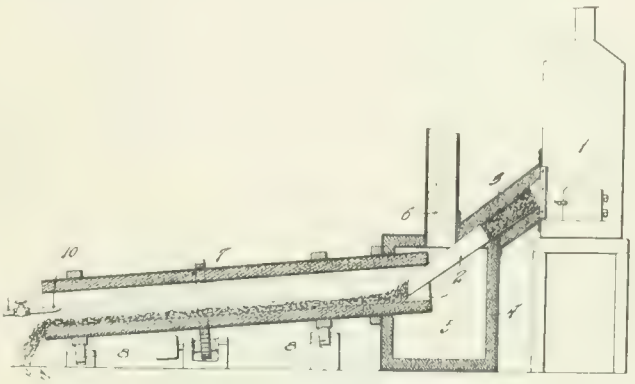

FIG. 4.—ZINC WHITE APPARATUS.

before the others, flexible connections are inserted between the conveyers and their driving shafts. (1,014,333, Jan. 9, 1912.)

Manufacture of Zinc White.—The continuous production of zinc oxide, or zinc white from roasted zinc sulphide ores may be accomplished according to the specifications of a patent granted to HARRY H. HUGHES, of St. Louis, Mo. In Fig. 4 we illustrate apparatus in which he proposes to carry out his invention. A roasting furnace is represented at 1, from which the roasted ore at a temperature of about 900 deg. C. is continuously discharged through the chute 3 into a revolving cylinder 7. The ignition of the hydrocarbon issuing from the nozzle 10 in the lower end of the cylinder brings the temperature up to approximately 1300 deg. C., which heat is necessary for the proper reduction of the ore to produce zinc white. This hydrocarbon flame acts as a reduction material, and the air drawn into the cylinder by the suction produced by the flame, together with the carbon dioxide produced by the combustion of the oil or gas, causes a reoxidation of the ore, thereby producing zinc white. Thus the zinc white is produced without adding any carbon or other reducing substance to the ore as in present methods. The zinc white fume passes out through the stack 6 and is condensed in suitable manner. Where carbonate, silicate or oxide zinc ores are used, no roasting is necessary, but a small addition of carbon may be mixed to give the proper reducing conditions. (1,014,062, Jan. 9, 1912.)

Bisulphite Process.—A modified form of the bisulphite process for zinc and copper ores is proposed by WOLDEMAR HOMMEL and HENRY T. DURANT, of London, England. Roasted zinc ore is mixed with water and brought in contact with sulphurous acid gas. The reaction forms zinc bisulphite, which is soluble and can be separated from the gangue of the ore. The solution is then subjected to the action of hot roaster gases, with two results: the gas is cooled so that it is available for the treatment of further ore and water; and the zinc bisulphite solution is broken up, giving sulphurous acid gas which enriches the furnace gas, and zinc monosulphite is precipitated. This is then collected and calcined to produce zinc oxide. The process has the commercial advantage of utilizing the heat of the roaster gases to precipitate the monosulphite, and of cooling and enriching the furnace gases for the treatment of ore. If the process is applied to copper ores, metallic copper will be precipitated instead of zinc monosulphite. (1,009,750, Nov. 28, 1911.)

Treatment of Refractory Zinc-Lead Ores.—A scheme for dissolving roasted refractory ores in zinc sulphate solution has been proposed by PERCY C. C. ISHERWOOD, of Leytonstone, England. There are some points in the process in which it seems as though mechanical difficulties would be encountered, but

otherwise the proposal is of interest. The inventor has discovered that the solubility of zinc oxide in zinc sulphate solution is greatly increased at temperatures above the boiling point of zinc sulphate and at pressure of from 50 to 200 lb. per square inch. As a result of this he finds that he can extract all the zinc from a mixed ore without contaminating his solution with iron. He proposes to roast ore so that a maximum of sulphate is formed, with some oxide and a minimum of sulphide. The roasted ore is then treated under conditions of temperature and pressure noted above, in a lead lined or enameled vessel, with less than the theoretical quantity of sulphuric acid necessary to dissolve all the zinc under normal conditions. The zinc sulphate formed is a good solvent for the oxide present, and if separated from the residue while still under pressure, and then allowed to cool, he finds that the excess of zinc will precipitate as basic sulphate. (1,011,962, Dec. 19, 1911.)

"Atomized Metals."

The manufacture of metals into a fine state of subdivision has been carried on in various industries for many years, but as the object aimed at was generally to obtain the metals in a condition readily susceptible to rapid oxidization, as for example, in the making of white lead pigment, etc., it required new conditions, etc., to develop a method by which the metals are obtained in an extremely fine state of subdivision, but unoxidized and in such a physical condition that even on exposure to ordinary atmospheric conditions they remain unoxidized. This new condition has been called *"atomized"* and the new process by which this condition can be obtained will be described in this article.

Atomized metals obtained by this process, are in such a physical state of activity, that their action in many industries may be strikingly likened to the action of ozone, while the same metals prepared by other methods are in their action similar to oxygen.

One industry to which atomized metals are especially adapted, is that of recovering the precious metals from cyanide solution obtained during the treatment of the ores by cyanide, and their application to this industry, marks a distinct and important advance in this art, through the elimination of the numerous imperfections and disadvantages existing under present conditions.

In order to understand the adapatibility of atomized metals to the art of cyaniding it will be well to give a short résumé of the numerous processes for the precipitation of precious metals from cyanide solutions; among these processes the following are those best known and in use throughout the world.

Zinc Shavings.—This process, one of the oldest—consists in converting metallic zinc into thin films or shavings, in which form it is placed in boxes through which the pregnant cyanide solutions are then allowed to percolate, with the resultant precipitation of the precious metals by replacement.

Lead-Zinc.—This process, invented by J. K. Betty, was used to some extent in South Africa with varying results. Its success depends upon the formation of an electro-galvanic couple by means of lead and zinc. This is accomplished by immersing strips of metallic zinc in a lead salt solution, usually lead acetate, whereby there is produced a deposit of metallic lead on the surface of the zinc, and this lead-zinc is then used in a manner similar to zinc shavings.

Zinc-Dust.—Prominent in the art of precipitation of precious metals from cyanide solutions stands zinc dust, its method of application or addition to the cyanide solution being the subject of numerous patents. Its efficiency is partially due to a small percentage of metallic impurities (usually lead), which have been carried over mechanically during the distilling operation, and as the always present zinc oxide is inert, it plays no part in the precipitation, being in fact detrimental, as it contaminates the precious metal precipitate and the solutions.

Zinc dust is the blue powder of the molten zinc formed in the distillation of the spelter. Its preparation consists merely in collecting the blue powder from the prolongs, as free from admixture with foreign material as possible, and then sifting. As its value depends upon the percentage of metallic zinc (zinc oxide being detrimental) it is essential in preparing it for this market to regulate the distillation and condensation of the zinc so that there will be the least possible formation of oxide. The market standard is a tenor of at least 90 per cent metallic *zinc*, but it is seldom as pure as this, the percentage of oxide being usually higher than 10 per cent

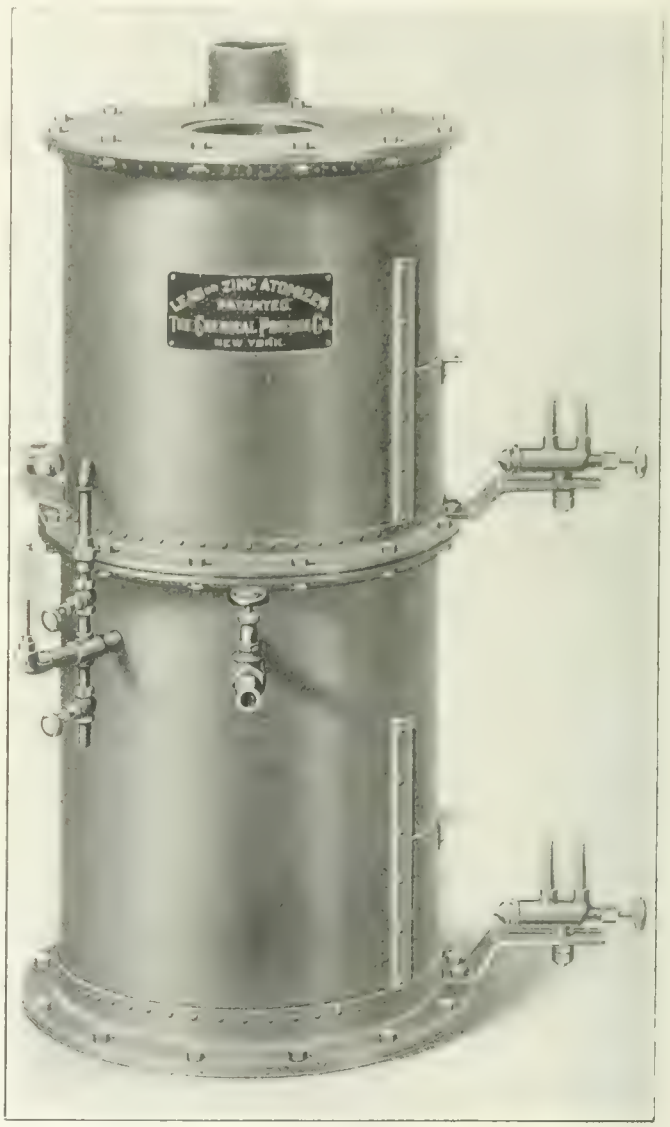

FIG. 1.—ATOMIZER.

Zinc dust is extremely susceptible to oxidation—so much so as to be explosive—and on that account great care and precaution is necessary in its transportation and storage. Owing to its inflammable nature and liability to spontaneous combustion it is rated by fire underwriters as a specially hazardous risk.

A new ruling of the Interstate Commerce Commission lists zinc dust and zinc flue dust as inflammable solids and directs that they must bear a yellow label. Paragraph 1834 of the ruling covering this product, reads as follows: "Packages must be tight and strong, and the interior packages must be so cushioned and secured that no rupture of either package can result from the ordinary shocks incident to transportation."

Notwithstanding the above mentioned disadvantages, the use of zinc dust in the process of precipitation has been preferred

to zinc shavings or the Betty lead-zinc process for the following reasons:

(a) The comparative cost of zinc dust and zinc is about 20 to 25 per cent in favor of zinc dust.

(b) Increased efficiency and decreased operative costs.

(c) In practice the consumption of zinc dust is not as great as that of zinc shavings.

(d) The re-solution of the precipitated precious metals when using zinc dust can be prevented by taking proper precautions.

(e) The system of using zinc dust minimizes the risk of loss of the precious metal precipitates from theft, fire, etc., permits of regular "clean-ups," conversion of the precipitates into bullion at any time and of accurate checks on the mill recoveries.

Having thus seen how great the advantages are of zinc dust over zinc shavings and lead-zinc, it only remains to show how preferable is the use of "atomized" lead and zinc over zinc dust. The superiority of atomized metals can be summed up as follows:

1. The production of atomized unoxidized lead and zinc, at will at a nominal cost, gives precipitating agents from which the maximum efficiency can be obtained.

2. The elimination of delays in delivery and of the dangers from spontaneous combustion and from explosion during transportation, storage, etc., and of the necessarily excessive freight charges when zinc dust is used.

3. Absolute control in the operation of precipitating the precious metals.

4. The elimination of the loss of zinc and of the contamination by oxide of the precious metal precipitates and cyanide solutions, as is the case in zinc dust.

5. The production and use of lead and zinc atomized of the same purity as the metals from which they are made.

6. The fact that pig lead and zinc from which atomized lead and zinc is produced are readily obtainable in any market.

7. The securing of any desired or required electro-galvanic action by the addition of the necessary amount of atomized lead to the atomized zinc.

8. The increased activity, efficiency and energy of the precipitating action of atomized lead and zinc is much greater than that of zinc dust.

9. The scrap zinc and lead usually found around the mill is readily converted into valuable atomized lead and zinc and thus profitably utilized instead of being disposed of as scrap metal.

10. The complete precipitation of the precious metals by the use of atomized metals.

11. The absence of the oxidization of atomized metals, as is the case with the use of zinc dust.

12. There being no absorption of water by atomized metals, the difficulties attending zinc dust are thereby lessened.

13. In using zinc dust experience has demonstrated that it is necessary to exclude the air, otherwise oxidation and secondary reactions occur, whereas in using atomized metals the exclusion of air is immaterial, as they can be used in any desired manner.

14. There is less consumption of acid in the final treatment of the precious metal precipitates. Microscropical examination shows that in zinc dust the particles of metallic zinc are surrounded by a film of oxide, which prevents any precipitating action, while the surfaces of the particles of atomized metals are bright and free from oxide, and in such a condition as to present the largest possible surface of metal for the immediate reaction of precipitation.

In collecting the precious metal precipitates any filter press may be used, but experience has demonstrated the superiority of the ordinary bottom filling press over any other.

In mills when cupellation is carried out atomized lead used for precipitation is of great benefit, as it reacts better, owing to its being well mixed with the gold and silver, and its state of fine division is also beneficial.

Atomizer.

The simplicity of construction and method of operation of the preferred form of "Atomizer" can be readily seen by referring to the accompanying photographs. Fig. 1 shows the atomizer ready for operation. Fig. 2 is a sectional view of the atomizer by means of which the following description will be easily understood:

The atomizer consists of an iron jacket divided into two compartments. The interior of this iron jacket is protected by a lining of fire bricks, having the necessary openings and connections.

The lower compartment is arranged, as shown in the illustration, so as to contain a superheating coil, surrounded and supported in position by fire bricks. In the lower compartment is also shown a combustion chamber, the upper compartment containing a superheating coil.

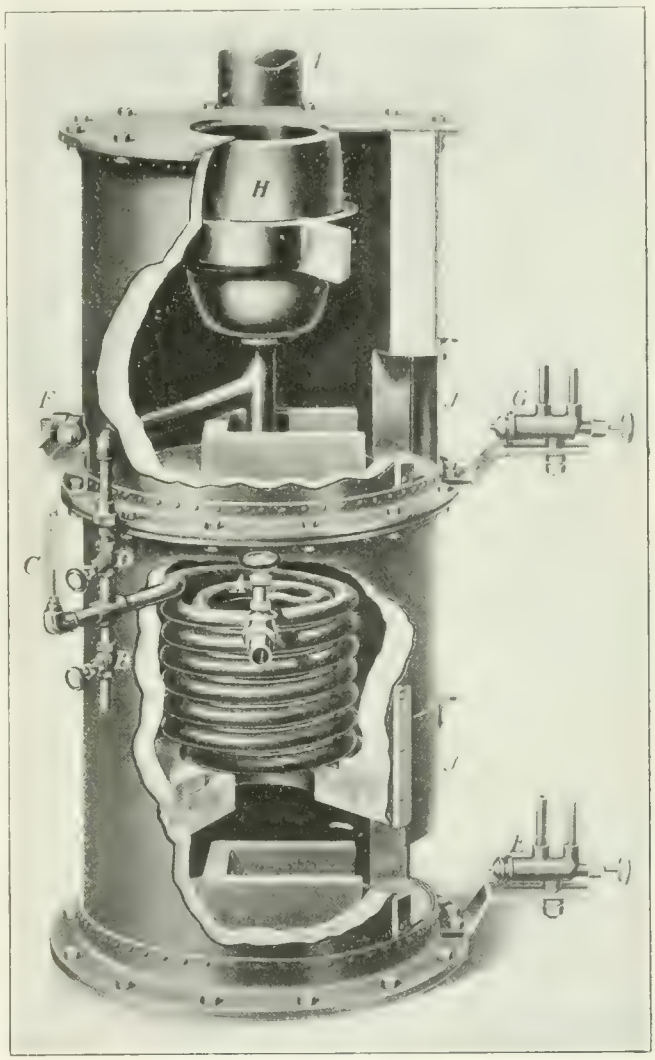

FIG. 2.—SECTIONAL VIEW OF ATOMIZER.

The superheating coil has a valve A placed so that the inlet of the steam or air to the superheating coil is regulated.

B is a drip valve, by means of which the steam or air passing through the coil is allowed to escape when it is not desired to pass the same through the atomizer.

C is a thermometer whereby the temperature of the steam or air being superheated is regulated.

D is a valve whereby the quantity of superheated steam or air required is admitted to the atomizer.

E is an oil burner to supply the necessary heat to the superheating chamber.

F is the metal atomizer.

G is an oil burner to supply the necessary heat to melt the metals undergoing treatment.

H is a crucible connected with the atomizer.

The upper chamber or compartment is simply a furnace to contain the crucible H.

Both the lower and upper compartments are connected with a chimney I to carry off the product of combustion from these compartments.

J J are doors whereby the temperature in either of these compartments may be regulated.

The atomizer is of special design, which allows of the molten metals first being formed into a film, before being atomized, thus insuring uniformity of product.

In operating the apparatus, heat is first applied by means of the oil burner to the upper compartment until the contents of the crucible commences to melt. Then steam or air is allowed to pass through the super-heating coil, and escape by the valve B. Heat is then applied to the lower compartment until the thermometer shows that the steam or air passing through the coil is at the correct temperature for atomizing. This temperature is maintained during the operation of atomizing.

Having thus reduced the metal to a molten state and with the steam or air heated to the necessary temperature, the metal is allowed to flow through the atomizer and then the drip valve B is closed and, by means of the valve D, the necessary amount of steam or air required to completely atomize the metal is allowed to pass through the atomizer into a collecting chamber.

When the superheated steam or air strikes the molten metal issuing from the atomizer, the metal is at once formed into a film and immediately atomized, leaving the atomizer in the form of a mist. This mist is deposited in the collecting chamber and on examination will be found to be in a pure unoxidized state of subdivision, its fineness being controlled at will by the operator.

The capacity of the apparatus shown is upwards of 100 lb. of atomized metal per hour.

The exclusive rights to the letters patents for the apparatus and the process of atomizing, and the process of using atomized lead and zinc in the precipitation of precious ore are owned by the Chemical Process Company, 170 Broadway, New York City.

The Use and Care of Crucibles in Foundry Practice.

Very little has been published on the manufacture and uses of graphite crucibles. A recent bulletin, issued by the Jonathan Bartley Crucible Company of Trenton, N. J., entitled "Crucibles and Other Graphite Productions for Foundry Use," is a notable exception. It is well written and well illustrated, and not only gives catalog data on the crucibles, retorts, etc., made by this company, but suggestive hints on the proper handling of graphite crucibles in foundry practice. The following information is taken from this bulletin:

Concerning the manufacture of graphite crucibles, much secrecy is preserved. Each manufacturer has his own secret formulas and methods. The margin of safety in computing formulas for different classes of work is very small, so that a slight deviation from a proper formula will prove disastrous. Different work requires different formulas; for example, a formula of composition which gives good results on steel will not give good results on brass; one suitable for nickel is not suitable for steel, etc. While analysis of the raw material is essential to produce a uniform crucible, an analysis of the crucible itself shows practically nothing beyond the limit of simple comparison. While chemical analysis is absolutely necessary, it is not everything, since a hundred different concoctions can be made that will apparently give the same analysis, but be widely different in physical properties.

Besides the careful selection of the raw materials in proper proportions, according to analysis, the manufacture of satisfactory crucibles also requires utmost care in the proper mixing of the raw materials, in the use of perfect molds and presses, and finally in proper and sufficient burning for the purpose of calcining the clay.

A laboratory test of the finished crucible amounts to nothing. The crucial test on which the crucible must stand or fall is made on the foundry floor, yet the life of a crucible in foundry practice depends to a large extent on the proper or improper use which is made of it by the founder.

The finished crucible has become hygroscopic as a result of the burning process. How much moisture it absorbs from the air will depend entirely on the atmosphere. In one instance a crucible, taken from a kiln of the Jonathan Bartley Crucible Company, was tested and found to contain less than one-quarter of one per cent. moisture, placed in a room where the temperature registered 90° F., and five hours later it contained two and seven-tenths per cent. moisture. It was then placed in the free atmosphere, and five hours later it contained four and one-half per cent. moisture. This illustrates the necessity of proper annealing of crucibles.

Every shop and foundry has its own method of **annealing** and this method depends very much on the conditions of the foundry. Thus, in one foundry few cores may be used and the oven can be almost entirely devoted to the annealing of crucibles; a second foundry might have an oven where cores are used extensively and the cores might be large. To place crucibles in an oven with a load of wet cores would be something in the order of putting a cat in the same cage with a canary bird. The crucibles would quickly absorb the moisture, and while it is true that a sufficient time and heat might eliminate danger to both, the practice is generally considered a dangerous one.

Another method of annealing which is quite popular among small foundries is to place a crucible on top of a furnace. This practice in most cases is all right provided the melter uses discretion. Crucibles, as a rule, when they arrive at a foundry contain from 4 to 5 per cent. moisture. If they are placed at once on top of a very hot furnace there is a chance of an immediate "scalp," and even if they should show no external damage, there might be caused an internal fracture which would in a few runs develop a leak, or what are commonly known as "pin holes."

The best device for annealing crucibles is a furnace built expressly for the purpose, using the waste heat from the foundry furnace on its way to the stack. These can be built so that the heat can be regulated and the temperature brought gradually from zero to or above 250° F. The average size crucible, say No. 60, should remain at this temperature at least 48 hours before going into the furnace. Larger sizes require more time.

The **tongs** require special notice. That they play a very important part in the life of a crucible is shown in the fact that in the tilting furnace, where the lifting in and out is eliminated, the crucible will run more than double the number of heats. Foundrymen as a rule are too careless in considering the importance of manipulating this end of their work.

When the crucible is under its melting heat it is plastic and readily adjusts itself to any irregular shape to fit the tongs. After a pour is made and the crucible cools off it will retain this irregular shape. In the second operation, unless the tongs are placed in the exact position, an unequal strain will occur, and if this is repeated time after time the crucible is weakened and naturally its life is shortened.

Different foundries have their own ideas as to the proper style of tongs best fitted for their work. But in any case utmost care is necessary to keep the tongs properly fitted to the crucibles. Reference is made to an exceptional case in which one pair of tongs handled three different sizes of crucibles in one shop. The loss in crucibles here would have paid for a dozen tongs in a short time.

In actual use there is nothing more detrimental to a graphite

crucible than the **fuel gases** that arise from impure fuel. Their effect permeates the entire wall.

Both coal and coke which contain sulphur to any great extent will produce this result, particularly if used in a wet or damp condition. Imperfect combustion with oil or gas will also act in the same way or even to a greater extent, due to the fact that in the coal or coke fire the crucible is almost completely submerged in the fuel and thus protected from extreme oxidizing conditions, so that the bad effect is obtained more at the top of the crucible, whereas in the oil or gas furnace imperfect combustion affects the entire surface.

These pernicious gases are always produced at low temperatures—usually in a coal or coke fire immediately after a fresh charge of fuel, and in the oil or gas furnace as a result of a slight manipulation of the air or fuel valves.

Great care should, therefore, be given to the fuel so as to have it as pure as possible, and perfectly dry, to charge it properly at the right time.

The life of a graphite crucible is oftimes greatly reduced by what is called in foundry parlance **soaking.** While this practice is more general among small founders, it is also observed to quite an extent in some of the larger plants.

At the beginning of the day's work the furnaces are fired, the charge made and the crucible placed. The molders begin their work; 9:30 a. m. finds the metal sufficiently melted for a "pour," but the molder is not ready, and it often occurs that two, three or four hours pass before the pour is made. All this time the crucible is simply living its life on wasted energy. Under a condition of this kind the ordinary life of a crucible can be divided by three.

The Latest Progress in Optical Pyrometry.

By Arthur Lenk, Ch. E.

The optical pyrometer has never had a keen rival in the thermo-electric pyrometer in the correct measurement of high temperatures, as so far no material is known that, if used as an armor, can permanently withstand prolonged and direct exposure to intense heat. A further aggravation of such difficulties is to be found in the chemical activities of furnace products and gases, which in many cases make an adequate protection of the thermo-couple entirely impossible. In other numerous instances in practice the temperature measurements cannot be made with pyrometers which must be brought into contact with the material operated upon, on account of its inaccessibility through being in motion. In all such cases, and where the temperature of large areas of hot masses must be readily measured, pyrometers acting at a distance are required, and if it comes to the measurement of exceedingly high temperatures, up to 7000 deg. C., only such instruments can be employed.

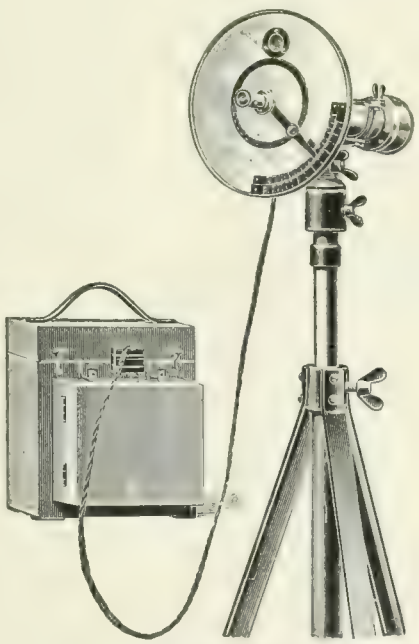

FIG. 1.—VIEW OF SCIMATCO OPTICAL PYROMETER.

The most important point in favor of all optical pyrometers based on the well-known formula of Paschen and Wien is the fact that their indications are not based on "ascertained properties" of certain materials, such as the thermo-electric forces of the thermo-couple used with radiation pyrometers, but on a well known infallible law of physics. As to the practical application of optical and radiation pyrometers, the former advantage of the radiation over the optical instrument through direct temperature readings on the Centigrade scale, in contrast with the readings from separate tables with the old optical type, has entirely disappeared with the recent improvement of the optical pyrometers through construction with direct-reading temperature scales.

FIG. 2.—SCALE OF SCIMATCO OPTICAL PYROMETER.

The application of the Paschen and Wien formula in a commercial instrument has until now been confined to one instrument manufactured in Germany, and most detailed researches have been carried on for the last few years with the view of improving and perfecting the same. The many careful tests made in the laboratories of the Reichsanstalt, as well as at the furnaces of the most prominent German glassworks, were highly successful and resulted in the introduction of a perfect type on the American market.

Some of the important improvements of the Scimatco pyrometers, which have a range of from 650 deg. to 7000 deg. C., may be mentioned here.

The direct temperature scale of the Scimatco pyrometer is permanently fixed to the ocular. The improved construction of the Scimatco permits a most perfect adjustment of the direct temperature scale.

The direct temperature scale of the Scimatco has the further great advantage that the scale shows not only the temperature, but also the angle, on which the reading is based, permitting a reliable checking of same. The temperature readings with the Scimatco are, therefore, at all times reliable.

The detachable screw-cap of the steel tube protecting the Scimatco pyrometer is also an important advantage over other instruments similarly protected. The small electric lamp has to be renewed frequently, and it is of great importance in practice that the renewing of the electric lamp in the Scimatco can easily be done in a few seconds, without tools. The electric lamp of the Scimatco pyrometer is enclosed in the protective steel tube.

The large disk of the Scimatco pyrometer fully protects both eyes. This is important since experts have declared that it

The temperature scale of the Scimatco is uniformly graduated in even numbers of degrees, thus facilitating readings and avoiding errors apt to occur with scales showing odd figures at irregular intervals.

The optical parts in the Scimatco pyrometer are inserted in the protective steel tube in such a way that they have no contact with the metal wall of the tube. If the instrument is used before large furnaces the pyrometers naturally become extremely hot. It is then of the utmost importance that the lenses and prisms which are partly cemented together be fully protected against heat and sudden changes of temperature. In the construction of the Scimatco pyrometer the necessary protection is not only rendered against the radiating heat by the surrounding steel tube, but even the conduction of heat is prevented, as the optical parts are separated by air from the heated metal walls of the instrument.

The screw-cap is absorbing the heat produced by the electric lamp and the small slit through which the light rays enter the pyrometer from the outside is constantly kept warm. There are, therefore, no expansions of metallic parts by heat with resulting changes of the size of the small slit through which the light enters the instruments. These would be a source of error because when a pyrometer is adjusted or standardized it is done in a laboratory, in a far lower temperature than the pyrometer finds in its practical applications. If the metal expands the slit gets smaller, and therefore the intensity of the light entering the instrument—the vital point on which the measurements are based—diminishes. The electric lamp in the Scimatco produces a constant temperature in the part bearing the slit and therefore successfully offsets the large changes in outside temperatures, while a considerable difference is caused in the dimension of the slit of other types through such outside influences.

The slit through which the light rays enter the Scimatco pyrometer is protected against dust and soot by a small glass slide of known optical properties, which have been most carefully investigated and fully approved by the Reichsanstalt. This device renders the instrument immune from dust and soot particles settling in the small slit and optical interferences caused thereby. If such protection is not employed, the use of such instruments in dusty atmospheres always gives rise to disturbances caused by dust and soot, a very disagreeable point, as it is difficult, sometimes impossible, to give the pyrometer a thorough cleaning. If the hair slit is covered by

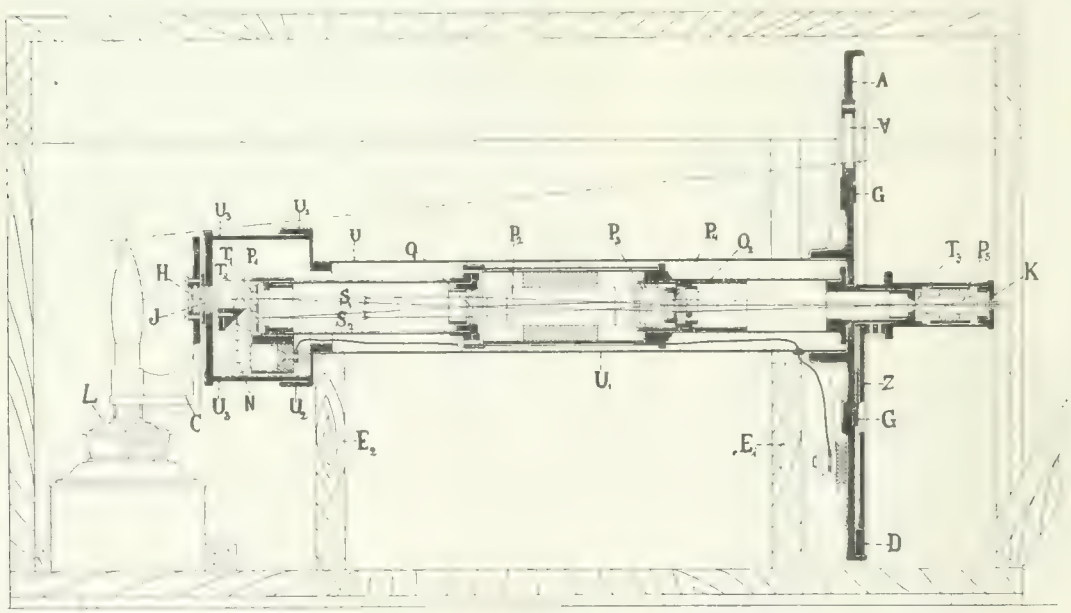

FIG. 3.—DETAILS OF CONSTRUCTION OF SCIMATCO PYROMETER.

the electric current is supplied to the small electric lamp of the Scimatco pyrometer. It has been fully ascertained that a great danger of fluctuations in the electric current exists, if the wires are attached to small leads to the contact of the lamp. First of all, the small leads cannot be properly and readily cleaned, and furthermore the wires are always more or less liable to tension, thus making the contacts unsafe and unsatisfactory. The system of supplying the electric current to the electric lamp of the Scimatco pyrometer is perfected in every way. The very large leads are fixed on the rear side of the temperature scale, where they can always be readily inspected, cleaned and tightened, and from there the wires are conducted to the lamp within the steel tube, fully protected against all disturbing influences.

The Scimatco pyrometer is constructed throughout in a very solid manner. The inner parts are fixed in such a way to the instrument that the whole arrangement acts like a spring whenever the apparatus suffers a shock through dropping, etc. Breakage of the Scimatco pyrometer is therefore hardly possible under the most straining circumstances.

Everybody familiar with the handling of optical pyrometers and realizing the many important improvements outlined above will readily see that the Scimatco instrument is the result of many years' research. It has been placed on the market in this country by the Scientific Materials Company, Pittsburgh, Pa

Purity a Requisite for Silver Electroplating Anodes.

By J. L. R. Brown.

The best way to show that "purity" is a requisite in a silver anode, is to point out some of the bad results arising from the use of impure silver, all of which bad results might have been avoided by the use of silver prepared for the purpose of plating and fully guaranteed. Let us review these bad results.

I am sure all electroplaters (especially in the old days) have had the disagreeable experience of contending with the presence on their silver anode surfaces of a black film attached so lightly that unless carefully handled it would float off into the solution, but which no amount of work, such as altering resistances, changing solution conditions or the many things one will do on occasions of this sort, could prevent. The only thing to do is to carefully remove them, wash thoroughly and replace, and continue this operation until the anodes are consumed.

Not all of the anodes would work this way, and sometimes not all of the surface of the anode would turn black. It would form in streaks alternating with clear portions, and under these conditions, the free cyanide would act correctly on parts of the surface and very little if at all, on others; at times eating through the anodes in the clean portions causing the black, where surrounded by the clean, to become detached and

to the bottom of the tank. The black way for an anode to go but a solution is, of course, to dissolve evenly all over the surface and to disappear from the edges, preserving the contour in the form of a regular curve.

The appearance of the silver anode before using is no guide in determining whether the anode will work white or not, as the surface of an anode which will work black is as clean and white before going into the solution as any other which is perfectly pure. In fact, there is little doubt but that the silver entering into a black anode is 0.999 fine, which it is necessary for it to be in order that it may be sold as "commercial silver." The term 0.999 fine, however, simply means that in every thousand ounces of bullion, there are 999 oz. of pure silver and 1 oz. of alloy. When this ounce of alloy is all, or partly composed of insoluble matter, the action of the free cyanide in the solution, dissolves out the silver in the anode, and leaves the insoluble matter in the shape of a black film on the surface. This will accumulate so rapidly when the anode is bad as to necessitate removal and cleaning as often as once a day.

I realize that silver anodes will turn black, when the silver from which the anode was made is absolutely all right. This may arise from a number of conditions, such as the action of sulphur in a bright solution, too high a current density for the work to be plated, or too much or a poor quality of cyanide. When the discoloration arises from faulty conditions in the plating room, it is of a different shade and easily distinguished, and a good plater can easily discover the cause and apply the remedy. The only remedy I ever heard for a black anode where the silver was bad, was to replace the bad ones with good ones.

Among the bad results arising from the use of impure silver, may be mentioned the following:

The increasing amount of resistance caused by this film lessens the rate of silver deposition and in the absence of scales at the tubs, the customer will get lighter plate than he pays for or than the plater intends to give him, or else, if the plater is careful to get the weight of silver on the goods, it takes him so much longer that the output of his department is lowered.

Further, the presence of this film retards the dissolving action of the free cyanide in the solution, and in a slight degree, the anode becomes neutral so that the silver is plated out of the solution at a greater rate than the free cyanide can replace it. I believe the first impulse of a plater, under this condition, is to increase the amount of free cyanide so as to take up the silver faster. This, however, is only a palliative and accomplishes no lasting good, as the solution is soon out of balance, and requires refining, and replacing by a new one.

One member of this association has told me of his solutions which have been in use nearly five years, and the quality of the anodes has been so uniformly good that in all that time he has not been obliged to supply any silver salts.

When the periodic cleaning of the black anode is neglected, the film becomes thick and floats off into the solution and not only contaminates it, but the dirt is carried over on the work. This makes it necessary to remove the goods and clean them with the danger of getting grease on the surface, and interfering with the smoothness of the plate. If the dirt gets on the goods and is not noticed, it is plated over and the plate blisters and tears out in burnishing or buffing, and requires stripping, refinishing and replating. That is what happens when you do not remove the anodes and clean them. Now if you do take them out, the action through the solution in lifting them, rinses the dirt off into the bath, and you get it anyway.

In the old days, when it was necessary to use any kind of silver which could be obtained, I understand it was the practice of some platers to hang a cloth curtain in front of the anodes to keep the dirt from floating over to the work, and while it would accomplish this purpose, it was still necessary to wash the anodes, and in addition the curtains needed washing, and the removal of the anodes and the curtains agitated the solution, and rinsed off the dirt. Of course, these troubles would not have arisen had the entire anode been soluble in the solution, as all of this residue must have been present in the anode when it was put in the solution, and the action of the cyanide solution taking out the pure silver in the plate, left the black residue, because the cyanide was not a solvent of it.

I know of electroplaters who bought the regular 1000-oz commercial bars, brought them to a low heat in a forge fire, put them under a drop hammer and flattened them to a point where they would enter their rolls and others who melted these bars, pouring the silver into flat shallow moulds thin enough to enter their rolls, and from this point, with suitable annealing rolled them to the right gauge and width, and cut to suitable lengths for anodes. Others bought what are known as Government assay bars, which are cast in a mould turning out a bar thin enough to be rolled without remelting. These used these bars feeling confident that silver bearing the stamp of the United States was the very best which could be obtained.

As a matter of fact, the government stamp on a bar of silver simply means that the melt from which that bar was poured was assayed and the fineness stamped on the bar is the result of such assaying. These bars may or may not contain insoluble matter, and are, therefore, we think, not the best silver for the purpose.

The point of view of the mints and the assay office is entirely a different one from our own. Our object is to establish a standard for anode silver and to uniformly maintain that quality; while the Government in refining the silver simply uses it as a carrier for the gold.

The proportion of silver in the dore which the Government requires in the process of gold refining used by them is so high that the immense amount of gold turned out by them requires a far greater quantity of silver, and this silver is furnished the Government absolutely free, and they are paid to use it.

One takes in gold and silver bars to be refined, they return to him the silver which they do not want, pay him for the gold which they do want and charge him for the refining. It is readily seen the only interest the Government has in the silver is to use it as an aid to their gold refining and to so carefully part the bars as to leave the silver free from gold and be able to turn it out 0.999 fine.

There are two branches of industry using silver which should have the purest which can be obtained to get the best results, one the electroplaters, and the other the manufacturers of silver nitrate; while at present the electroplaters use the larger amount, yet as a result of the recent popularity of the moving picture show, of the almost universal use of the picture post card (I speak of the sensitized kind) and of the coming among us in such large numbers of the amateur photographer, the consumption of silver in the manufacture of nitrate is much larger than is generally known.

Notwithstanding the fact that silver plating was being done commercially over 60 years ago, there was no concern manufacturing and marketing silver anodes as a commercial article until the author's firm originated the idea, and so far as I know, made the first silver anodes for sale as such at their plant which was then located in Chicago.

In talking with a plater, who at the time was engaged in washing off his anodes and skimming his solution, we asked if it would not be a good thing if an anode could be made which would always work clean and white and guaranteed by the manufacturer to be uniform from lot to lot. From the encouragement received at this time, we commenced experimenting and after numberless discouragements and expensive experiment we succeeded in 1903 after we had moved our plant to Bridgeport, Conn. Since then, we have made and sold tons of anodes, every ounce of which is thoroughly guaranteed.

The silver requires very careful selection to start with and careful handling all through the process. There is very little silver ore which is mined and smelted as such, the value per ton not commercially warranting the operation. There are exceptions to this, of course, the most noted one being the mines

located in the Cobalt district. In many of these, the total cost for mining, smelting, and marketing the silver, is from 12 to 25 cents per ounce. The present level of the silver market (at around 60 cents per ounce) permits the operation of these mines at quite a fair profit.

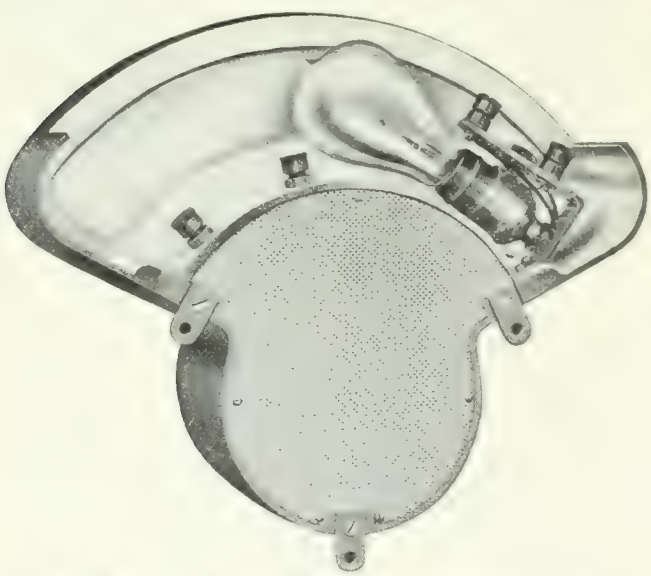
The bulk of the silver used by our firm, I think I may safely say nearly 85 per cent, is produced as the result of smelting lead, copper and others ores, where the silver is left behind in the slimes with any impurities. Naturally as the ores vary a great deal in impurities, depending upon the locality from which they are mined, so also the impurities accompanying the silver will vary, and while some silver is suitable for anode purposes, others, owing to the excessive cost of suitably refining, are prohibitive, while others in turn cannot be used at all. The success depends on being able to select the right kinds, and rejecting the wrong kinds, in fact in knowing how.

Handy & Harman,
New York City.

Illuminated-Dial Pyrometer

The Brown Instrument Company of Philadelphia are adding to their very complete line of electrical pyrometers, a new illuminated dial indicator, with exceptionally long scale. Frequently an instrument is desired which can be easily read by the operator of the furnace or kiln, at some distance, and the new Brown pyrometer with illuminated dial is particularly desirable for just such conditions.

This new instrument with extra long scale 12 in., can be furnished with or without illuminated dial as desired. Where the



BACK OF ELECTRIC PYROMETER WITH ILLUMINATED SCALE

illumination is sufficient, the instrument does not require an illuminated dial, but the long scale affords very open graduations and accurate readings.

In many plants, however, such as dark shops for hardening and heat treating steel, and where work is carried on day and night, the illuminated-dial instrument is preferable. The scale is drawn on opaque glass, and a 16-candle power lamp, placed behind the scale, makes the graduations and the pointer stand out clearly at a distance. The operator using the instrument appreciates the advantages of such an instrument, and better results are secured through the ability to obtain more accurate readings of the temperature.

The Iron and Steel Market.

The active steel market which was expected this year has not materialized. February has not proved better than January, and while both months represented better conditions than prevailed, on an average, during the second half of 1911, there has not been the return to the active conditions of November and the fore part of December that was expected.

The mills have been operating in the past two months chiefly on the accumulation of business in the closing months of last year, but there has really been a fair amount of business done, chiefly by way of specifications being entered on contracts then placed. Of strictly new buying there has been relatively little.

Mill operations have steadily increased in the past two months, from an average of 75 per cent to full capacity, maintained quite steadily during the fourth quarter of 1911, to about 85 per cent at the present time. Much of the additional capacity was nominally put in operation in January, but on account of extremely severe weather outputs did not correspondingly increase, but rather were somewhat smaller than in December. Toward the close of February actual outputs became decidedly more satisfactory.

The mill activity has not been equally distributed by any means. The heaviest pressure has been in the Steel Corporation mills in the Pittsburgh district, partly on material for the large number of cars placed with the car shops in October, November and December, and partly on export business, with which the Steel Corporation continues to be well supplied. Independent producers in the Central West have been operating fairly well, while the Eastern mills, as a rule, have had very light operation, generally ranging from 50 to 65 per cent of capacity.

The merchant furnaces have not increased their production as compared with last year, thus being in a distinctly different position from the steel interests. It is now possible to estimate with considerable accuracy the extent and importance of the buying movement which occurred in November and December. It has been made evident that it did not represent any actual increase in the country's rate of ultimate consumption of iron and steel products. Two influences were present. In the first place, prices all along the line had dropped to the lowest point since 1899, and in a few cases to levels lower even than the historic low levels of 1897 and 1898. In the second place, a number of railroads made fairly large purchases of cars and smaller purchases of other material. While in this action they may have been moved partly by the need of equipment and partly also by the very low prices prevailing, there is no doubt that there was a definite understanding among some important men of affairs that it would be of general advantage if the market were given a stimulus by the placing of some large orders. Through these two influences a buying movement was started in other quarters by jobbers and manufacturing consumers. Thus the active conditions of November and December did not represent a definite increase in the rate of consumption, but a burst of buying which was necessarily temporary in its character.

There is reason to expect an improvement in demand in March and April, but even that would not prove that the present year was marked for one of continued high activity, for the reason that consumptive requirements along certain lines have been accumulating on account of the extremely unfavorable weather, retarding or entirely stopping outside operations. Many large jobs have fallen a month or more behind their schedules, and with spring weather efforts will naturally be made to catch up. Thus a sudden increase in demand may occur in the near future, but it is also quite possible that provision has already been made for this increase, and that in anticipation the mills have made more material, and the buyers have taken more material, than was currently needed in the past two months.

Nominal prices for finished steel products have suffered to the extent of declines of about a dollar a ton in bars, plates, shapes and sheets. These are real declines, to the extent that material could not have been bought at present prices thirty days ago, but they are not declines from the average prices prevailing on material recently shipped, for shipments have

been almost entirely upon purchases made before the advances in December, and the market remains quotably higher on several prices, and in no cases lower, than the level prevailing at the low point in November. Plates, bars and shapes, however, are now quotable at 1.10c., Pittsburgh, against 1.15c. at the close of December, while sheets are quotable at 1.85c against 1.90c

Pig Iron.

The pig iron market has been dull throughout February, but in this respect no change was shown from January. The merchant furnaces have not increased their production as compared with January or December, but are shipping their product as fast as made now as was the case in those months. During 1911 stocks at merchant furnaces decreased and the statistical situation is good. It would require only a slight increase in actual consumption, probably to send prices up fractionally, but no large advance is possible on account of the many furnaces idle. With each advance of, say, 50 cents a ton, a considerable number of furnaces would resume operations. The merchant furnaces are much interested in ore price prospects for the coming season. Most of them have considerable stocks, but of course will have to buy for the season. For last season several central western furnaces did not buy at all. There will be a reduction in Lake Superior ore prices for the season, as compared with last year. The rail rate from the Mesabi range to Lake Superior was recently reduced 20 cents, which saving will be given to consumers of Mesabi ore, while the dock charges at Lake Erie ports are likely to be decreased by about 10 cents through an expected order of the Interstate Commerce Commission, which would reduce the cost of delivery of ore from all the ranges. Apart from these reductions Lake Superior ore on Lake Erie dock will be lower, probably by from 50 to 75 cents on Mesabi and 25 to 50 cents on old range. In the past two years the eastern furnaces have been using imported ore. With the advance in ocean freights and in ore prices at foreign mines, together with the expected reduction in Lake Superior ores, there has been a chance for the Lake Superior ore interests to regain a portion of the eastern trade. When, however, they approached the eastern furnaces with promise of a reduction, the eastern furnaces reflected that this would give the Buffalo district cheaper ore also, and thus place the eastern furnaces at a disadvantage, when competing with the Buffalo furnaces in New England territory. The freight on ore from Lake Erie to most of the eastern furnaces is $1.45, whereas last year the eastern furnaces obtained foreign ore costing less per unit than the cost at Buffalo, plus the $1.45 freight. The next move of the Lake Superior ore interests was to appear before the Finance Committee of the Senate, in the tariff hearings, and ask that the ore duty be made 50 cents. It was 75 cents in the McKinley law of 1890, the Wilson-Gorman law of 1894 and the Dingley law of 1897, being reduced to 15 cents by the Payne-Aldrich law of 1909. Since the independence of Cuba was established that country has had a preferential of 20 per cent, making the present duty on Cuban ores 12 cents. The Underwood bill which recently passed the House placed ore on the free list. Naturally, there is no likelihood of Congress at this time making an advance in the duty, and particularly an advance to a rate higher than has prevailed for nearly 18 years. Pig iron is quotable as follows: Southern iron, $10; Birmingham, for prompt, with $10.25 to $10.50 asked for second quarter; No. 2X foundry, Philadelphia, $14.75 to $15; No. 2 foundry, f. o. b., Buffalo furnaces, $13.75; No. 2 foundry, f. o. b. Chicago furnaces, $14; f. o. b. valley furnaces (90 cents higer delivered Pittsburgh); No. 2 foundry, $13 to $13.25; gray forge, $12.50 to $12.75; malleable, $13 to $13.25; basic, $12.25 to $12.50; Bessemer, $14 to $14.25

Steel.

Consumers are well covered by contracts for billets and sheet bars, but in many cases are not receiving full deliveries, and there has been considerable demand for small lots for prompt shipment. These would perhaps command a slight premium over forward deliveries. The market stands approximately as follows: F. o. b. maker's mill, Pittsburgh; Bessemer and open-hearth billets, $20 to $20.50; Bessemer sheet bars, $21; open-hearth sheet bars, $20.50 to $21; f. o. b. maker's mill, Youngstown; Bessemer billets, $19.50 to $20; Bessemer sheet bars, $20 to $20.50. Wire rods are nominally $25, Pittsburgh.

Finished Material.

Current prices, f. o. b. Pittsburgh, unless otherwise stated, are as follows, and are fairly well maintained:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mills, except Colorado.

Plates, tank quality, 1.10 cents; Chicago, 1.25 cents.

Shapes, 1.10 cents.

Steel bars, 1.10 cents; 1.25 cents, Chicago.

Iron bars, 1.25 cents, Pittsburgh; 1.25 cents, Philadelphia; 1.15 cent, Chicago.

Wire nails, base, $1.60; plain wire, 1.40 cents, base.

Black sheets, 28-gage, 1.85 to 1.90 cents; galvanized, 2.85 to 2.90 cents; painted corrugated roofing, $1.33 to $1.35 per square; galvanized, $2.47 to $2.50 per square.

The Non-Ferrous Metal Market

The February metal market was characterized principally by a marked reduction in lead, made by the American Smelting & Refining Company. Business in the tin and copper markets was only fair, but in lead and spelter there was considerable activity.

Copper.—The feature of this market was the nominal quotation and light demand for Lake copper. Electrolytic was in considerable demand both for European and domestic consumption. With the reduced prices for electrolytic, the business done in Lake was insignificant. The latest quotations are slightly higher than those which prevailed early in the month. Electrolytic, 14.08 cents; Lake, 14¼ cents.

Lead.—All the selling agencies were forced to meet a marked reduction made by the American Smelting & Refining Company, and the market has been active at 4 cents, New York, and 3.87½ cents, St. Louis.

Tin.—This metal was available in quantities to suit, and the premium for spot metal was removed. February tin was quoted at 43⅛ cents.

Spelter.—Large demands for future delivery have been met by the smelters, and there has been a premium demanded in some cases for spot metal. The market for current delivery was active at 6.50 cents, New York, and 6.35 cents, St. Louis.

Other Metals.—Business in aluminium and antimony has been quiet, but quicksilver has enjoyed an advance in price, with steady demand. The latest quotations are: Aluminium, 19 to 19½ cents, New York, for No. 1 ingots. Antimony, 6¾ to 7⅜ cents for various brands. Quicksilver, $44 per flask of 75 lb., New York, and $43.50, San Francisco.

Personal.

Messrs. Philip Argall & Sons, Denver, Col., have been appointed consulting engineers in charge of the properties owned by the estate of the late David H. Moffat, of Denver, Col.

Mr. Gelasio Caetani, of San Francisco, has been at Telluride, Col., on professional business at the large mills there. Mr. Caetani recently has entered into partnership with Albert Burch and Oscar H. Hershey under the firm name of Burch, Caetani & Hershey, consulting engineers in mining, metallurgy and mining geology. Their offices will be in the Crocker Building, San Francisco.

Mr. George E. Collins has returned to Denver from London

Mr. George A. Guess has been appointed professor of metallurgy in the Toronto University, Canada.

Mr. William G. Haldane, assistant professor of metallurgy Colorado School of Mines, was married on February 28 in Denver to Miss Lorena V. Beaver.

Mr. Carl Hering, the distinguished consulting electrical engineer of Philadelphia, has received from the University of Pennsylvania the honorary degree of Doctor of Science. Dr. Hering is a past president of the American Institute of Electrical Engineers and of the American Electrochemical Society.

Mr. Richard A. Parker has returned to Denver from a professional trip into Arizona.

Mr. W. C. Patterson, of London, patentee of Patterson agitation tank, is now located at Denver, Col., where he has a testing plant at the works of the McFarland Manufacturing Company, 3309 Blake Street, Denver, Colo.

Mr. Frank H. Probert has returned to Arizona following a trip to New York, where he was in consultation with the officers of the Ray Central and Proprietary Mines companies.

Mr. Frank E. Shepard, of the Denver Engineering Works Company, addressed the mining men of Telluride, Col., on Feb. 23. His subject was "Modern Mill Design."

Mr. F. M. Simonds, of New York, was in Denver recently on his way to examine the Rawley mine, near Salida, Col. While in Denver he investigated late improvements in ore dressing.

Mr. Norval J. Welsh, of San Antonio, Tex., has been appointed general manager of the Mexican Mines Development Company, operating in the Santa Eulalia district, Chihuahua, Mexico. His headquarters will be at 229 Avenida Independencia, Chihuahua, Mexico.

Obituary

Col. A. G. Brownlee, of Idaho Springs, Col., died at his home at the Stanley Mines, near Idaho Springs, on January 16, 1911. Col. Brownlee was a prominent operator of Colorado mines and mills, having been connected principally with the Japan-Flora property in the Telluride district, and with the Stanley at Idaho Springs. He was interested in the development of metallurgical processes, especially such as gave promise of treating successfully mixed sulphide ores, and in the last three years had given time and money to the application of dry chlorination. He was a director and vice-president of the American Mining Congress, and a past president of the Colorado Scientific Society.

NOTES.

Capacity of the Sulphur Mine of the Union Sulphur Co.—In Mr. Herman Frasch's paper published in our February issue there appears on page 78, second column, the following paragraph: "In order to demonstrate what the mine could do with six wells, we pumped that number simultaneously for *six months,* producing 122,000 tons of sulphur, which is more than the consumption of the whole world for that period of time. The words "six months" are a typographical error and should read *"two months."*

The occurrence of lorandite in the Rambler mine, Wyoming, has been established by Mr. Austin F. Rogers, who publishes his work in the February, 1912, issue of the *American Journal of Science.* The Rambler mine has been remarkable for its great variety of copper minerals, together with minerals of the platinum group. The determination of the occurrence of lorandite adds another rare mineral to the long list. This is a metasulpharsenite of thallium, $TlAsS_2$. The only other known occurrence of lorandite is at Allchar, in Macedonia.

The Dwight-Lloyd sinter-roasting furnace has been adopted in connection with the manufacture of sulphuric acid. [illegible] content, averaging about 4 to 6 per cent SO_2. A large plant has been erected at Stolberg, Germany, in which these furnaces will be used in connection with the contact process. The Huntington-Heberlein roasting process also is used in acid manufacture, but the conditions are not so favorable as with the Dwight-Lloyd apparatus.

The consumption of sulphuric acid in European countries has increased in the past few years owing to the increased development of the superphosphate industry, and to the increasing number of coke ovens which manufacture by-products

Calendars.—Quite a number of very artistic calendars for 1912 have been received. That of C. W. Leavitt & Company has an interesting picture of a 15-ton Girod electric steel furnace. The calendar of the Roessler & Hasslacher Chemical Company contains the international table of atomic weights for 1912, besides a fine picture by Coomans, while John MacWhirter's "Gates of the Forest" is found on the very artistic calendar of the Ashland Fire Brick Company. The calendar of the Goldschmidt Thermit Company has a map of the world and interesting photographs of thermit welds; the calendar of the Denver & Rio Grande Railroad shows a series of striking and stunning views of scenes along this "scenic railway of the world."

The Wellcome Photographic Exposure Record and Diary for 1912, issued by Burroughs, Wellcome & Company, of New York and London (price 50 cents), is as neat and interesting as any former editions of this annual. The information on photographic subjects which it contains within a small space is really remarkable. Attention is confined by no means to one plate or one method; on the contrary, brief and explicit instructions and explanations are given on such diverse topics as factorial and time development, machine, tank or stand development, the oil pigment process, contact printing by artificial light, color photography, development in warm weather and in tropical countries, printing and toning, color effects by staining, the actinic value of light in various latitudes, etc. The Wellcome exposure calculator is again added.

The McGraw-Hill Book Company announces the completion of arrangements for the sales agency of the technical books of the *Railway Age Gazette, American Engineer* and *Signal Engineer.* This makes the McGraw-Hill Book Company, publishers and distributors of books for the three journals, but it does not affect the publication of the papers themselves in any way. With the addition of these three papers in the railroad field, the McGraw-Hill Book Company now publishes books for the twelve leading American engineering papers in the fields of civil, mechanical and electrical engineering, electric and steam railroading, machine tools, mining, metallurgy, chemical engineering, etc. The papers now represented are *American Engineer, American Machinist, Coal Age, Electric Railway Journal, Electrical World, Engineering News, Engineering Record, Engineering and Mining Journal, Metallurgical and Chemical Engineering, Power, Railway Age Gazette, and Signal Engineer.*

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (*Continued*).

531,169, Dec. 18, 1894, Victor Engelhardt, of Vienna, Austria, assignor to Siemens & Halske, of Berlin, Germany.

Antimony and Arsenic; also gold, platinum, tellurium, molybdenum and tin, from sulphide ores. The ground ore is dissolved, with agitation and at a temperature of 212° F., in sodium

sulphydrate, with evolution of hydrogen sulphide. The solution is filtered and electrolyzed in a cell having a diaphragm of sheet asbestos boiled in gelatine, the anodes being of carbon or platinum, in a closed compartment, the cathode of copper or antimony. The antimony or arsenic are electrodeposited, with regeneration of the sodium sulphydrate. If the ores contain gold, silver, copper, mercury, bismuth, zinc, cobalt or nickel, the anode electrolyte may be an alkali-metal chloride, and the evolved chlorine is then removed and used to dissolve these metals from the residue undissolved by the sulphydrate. The chloride solution is filtered and the metals are precipitated by hydrogen sulphide from the first operation.

537,423, April 9, 1895, F. H. Long and D. C. Skaden, of Chicago, Ill., Long, assignor to A. G. Long.

Precious metals. Dissolves and deposits the metals electrically in a horizontal tumbling drum. The inside of the drum is lined with carbon plates having ore-lifting wings, serving as cathodes. Supported axially within and rotating with the drum is a perforated iron tube, serving as cathode, and surrounded by a jacket of asbestos cloth. Within and fitting this tube is a fixed screw-conveyor. In use, the ore pulp, mixed with some chlorine-generating substance is introduced into the drum, which is set in rotation. The metals are dissolved by the evolved chlorine, and are redeposited in the perforated iron tube, from which they are scraped off and carried out by the conveyor, one end of the tube opening through one head of the drum. A fixed gas vent pipe extends through the other head.

538,522, April 30, 1895, Edward D. Kendall, of New York City.

Gold and Silver. Precipitates from cyanide solutions by amalgamated zinc granules, turnings, filings or shavings. The residue zinc is removed from the precipitate by covering it with granulated hard carbon and adding dilute sulphuric acid.

543,546, July 30, 1895. Edwin J. Fraser, of San Francisco, Cal.

Gold and other precious metals. Precipitates from acidulated solutions by passing them longitudinally through a cylindrical vessel containing the elements of a voltaic pile, to wit, perforated zinc plates covered on both surfaces with cloth, alternating with bodies of pulverized charcoal.The end electrodes are preferably connected by a wire.

543,673, July 30, 1895, Middleton Crawford, of Colorado Springs, Colorado, Assignor of three-fourths to Thomas C. Parrish and Duncan Chisholm, of same place, and James Pourtales, of Silesia, Germany.

Relates to the cyanid process as applied to gold ores, the invention consisting in using an electric current to increase the activity of the cyanid solution before it is employed for lixiviation. It is stated that during electrolysis of a weak solution of potassium or other soluble cyanid, between an anode of carbon and a cathode of copper or iron, the electrodes preferably separated by a diaphragm, the solution surrounding the anode acquires greatly increased solvent powers of gold, with "no corresponding increase, but rather a decrease in the facility with which the various cyanid salts of the base metals are formed." The solution surrounding the cathode may consist of potassium cyanid or sodium sulfate. The effect at the anode is attributed to the formation of a certain proportion of cyanate, the oxygen of which is thought to be available for the solution of gold in accordance with Elsner's equation. Satisfactory results are secured when the proportion of cyanate to cyanid in the treated solution lies between 25 and 100 per cent. The data given in the patent would indicate an enormous increase of the activity of the liquid, as compared with pure cyanid. Following the lixiviation, any larger particles of gold may be recovered by amalgamation, preferably aided by the electric current, during which process some of the dissolved gold may be precipitated upon the mercury. The gold is then completely precipitated by electrolysis, and the solution regenerated. The advantages alleged for the process, in addition to the saving of time in lixiviation, are an increased stability of the solvent, the facility of regeneration of the liquid, and the producton of somewhat purer solutions of gold.

543,674, July 30, 1895, Middleton Crawford, of Colorado Springs, Colorado, Assignor of three-fourths to Thomas C. Parrish and Duncan Chisholm, of same place, and James Paurtales, of Silesia, Germany.

Relates to the solution of gold by the conjoint action of cyanid and cyanate of potassium, as in the preceding patent (543,673), the distinctive point of the invention being that the desired percentage of cyanate is added directly, as such, to the solution of cyanid. The proportion of cyanate, and the advantages attending its use, are as in the preceding patent.

543,675, July 30, 1895, Middleton Crawford, of Colorado Springs, Colorado, Assignor of three-fourths to Thomas C. Parrish and Duncan Chisholm, of same place, and James Pourtales, of Silesia, Germany.

An apparatus for treating gold ores by a solvent liquid, presumably the combined cyanid and cyanate of patent 543,673. The apparatus comprises two or more rotary barrels of wood, with provision for introducing the solvent through their trunnions. Following the treatment with the solvent liquid the contents of the barrels are discharged alternately upon a vibratory amalgamator for the recovery of any coarse gold. The tailings from the amalgamator are separated from the solvent liquid by filtration, and the latter is passed through an electrolytic cell in which the precious metal is precipitated. The solvent, thus regenerated, flows into a storage tank whence it is returned to the solution barrels.

BOOK REVIEWS.

A Manual of Fire Assaying. By **C. N. Fulton,** Professor of Metallurgy, Case School of Applied Science. Second Edition, 6 x 9¼ in. (15 x 23½ cm.), 219 pages, 60 illustrations, price $2.00, net. New York. McGraw-Hill Book Company.

In noticing the first edition of this book, we commended it as the first truly scientific and satisfactory work on assaying, treating the subject from the modern standpoint of exact science, in place of the old rule-of-thumb, cook-stove-recipe style. It should suffice now to say that the second edition, entirely rewritten and enlarged, is better than the first. *Nuf sed.*

Journal of the Municipal School of Technology, Manchester.—A record of investigations undertaken by members of the teaching staff and students of the school during 1910. Vol. IV, 253 pages.

Among the papers published in this volume there are the following: On the condition of indigo white in aqueous solution, Edmund Knecht; gravimetric methods for the determination of nickel in nickel steel, E. L. Rhead; apparatus for the study of gas-caps on the flame of an ordinary safety-lamp, G. H. Winstanley; crysallized caustic soda, F. S. Sinnatt; electrical theory of dyeing, W. W. Haldane Gee and W. Harrison; researches on bleaching powder, R. L. Taylor.

* * *

Technology and Industrial Efficiency. Papers presented at the semi-centennial of the Massachusetts Institute of Technology; 6 x 9 in., 486 pages; price, $3. New York: McGraw-Hill Book Company.

A collection of 59 papers, all written by graduates of the Institute, and presented at a technological congress held in Boston, April 10, 1911, to celebrate the fiftieth anniversary of the Institute.

There is an address by President Maclaurin on "The Factors of the Institute's Success," followed by seventeen papers on "Scientific Investigation and Control of Industrial Processes," thirteen on "Technological Education in Its Relations to Industrial Development," nine on "Administration and Management," fifteen on "Recent Industrial Development," nine on "Public Health and Sanitation," and four on "Architecture."

The range of subjects and high standing of many of the writers make this a very attractive book for those desiring a general review of the present relations of applied science to industry, commerce and public utilities.

* * *

The Heat Treatment of Tool Steel. By **Henry Brearley.** 5½ by 8¾ in., 160 pages, 73 illustrations. Price, 10/6 net ($3.50 net in New York). London and New York: Longmans, Green & Company.

The author has been twenty-seven years in the employ of Thomas Firth & Sons, Sheffield, and is now in charge of their research laboratory. His thirteen chapters deal with structure and classification, fractures and external appearance, forging, annealing, physical changes, hardening of steel, tempering, hardening typical tools, defective tools, hardening plant, pyrometers, case-hardening, alloy steels.

On inspecting the work we are impressed by the very clear, practical manner in which it is written. The absence of speculative theory and the directness of the information. It is admirably adapted to teaching students and beginners the principles and practice of the subject, and for explaining to tool-steel workers the real reasons for the manipulations practised in their trade.

The Metallurgy of Iron and Steel. By Bradley Stoughton, Ph.B. Second edition, thoroughly revised and entirely reset, 6 by 9 in. (15 x 23 cm.), 537 pages, 370 illustrations. Price, $3.00. New York: McGraw-Hill Book Co.

Mr. Gaughton gave a pretty satisfactory book in his first edition, and this second edition is still better. There is a new chapter on Metallurgical Fuels (well condensed), a better statement of the theory of the Bessemer process, and a new section on special open-hearth and duplex processes (brought well up to date). On page 473, the statement that 1 caloric per cubic meter = 8.9 B.t.u. per cubic foot is upside down; similar looseness in giving numerical date is observable in other places, such as 7,110,000 for 711 on page 33. These are, however, very minor defects in a book which as a whole, particularly on the descriptive side, is excellent and reliable. It is a particularly useful book for students' use, when supplemented by lectures upon the finer points of the subject. The publishers are to be commended for the fine typography and the low price.

* * *

Grundzüge des Eisenhüttenwesens. Von Dr. Ing. **Th. Geilenkirchen.** I Band. Allgemeine Eisenhüttenkunde. 249 pages, 66 cuts, 8 plates. Bound in cloth. Price, 8 marks ($2.50 in New York). Berlin: Julius Springer.

The complete work is to consist of three volumes, the whole intended as a strictly scientific exposition of the principles of iron metallurgy, omitting general descriptions and merely historical material. The three sections of this first volume treat respectively of industrial kinds of iron from the standpoint of the consumer, a compilation of the occurrences of iron ores in nature, together with a short review of the theoretical possibility of producing commercial iron from such raw materials, and finally the ways and means of producing and using heat as the agent of metallurgical operations.

The whole scheme is grandiose, but rather vague; the detail, as exemplified in this first volume, is hardly satisfying to the reviewer. It takes industry to compile satisfactorily, to fill out a larger scheme, but genius to select and condense. The author has not selected his subjects carefully enough, nor does he treat them in a masterly manner. Only one-quarter of this volume, for instance, is devoted to the highly important subject of the composition and properties of commercial iron, one-tenth to the sources of supply in nature, and over one-half to the discussion of fuel, coal, coke, producer gas, and the principles of combustion.

Inspecting the details, we find much imperfect and some erroneous information in the discussion of the properties of iron, the subject of oxygen and nitrogen in iron and the causes of blowholes in steel suggests a resumé of current knowledge twenty-five years ago. The description of ore deposits is in parts very faulty and misleading, as, for instance, the statements that the Mesabi ores are "free from phosphorus and sulphur," and that ores of similar quality are found "in Alabama, on the Atlantic Ocean." In the discussion of fuels and combustion, sensible heat of hot gases is called "latent heat" (page 197), and other loose expressions are observable which are not "strictly scientific."

We cannot, in conclusion, praise the book; it contains poorly selected material unskilfully condensed. The three volumes together will be perhaps three-quarters as large as Ledebur's "Eisenhüttenkunde," and probably about one-quarter as good, judging from Volume I as a sample. Let us hope that this extrapolation in judgment will prove wrong.

Engineering as a Vocation. By **Ernest McCullough,** C.E. Size, 5½ in. x 8 in. (14 cm x 20 cm), 291 pages. Price $1.00. New York: David Williams Company.

This book is a mixture of advice to young men intending to enter engineering, of information for the benefit of parents, and of some good and some poor ideas on engineers and engineering. The eight chapters deal with the engineer and his work, his education in schools, his self-education; "how to hunt and hold a job" and finally with the worthless discussion as to whether it pays to study engineering.

In discussing the education of the engineer the author states that splendid opportunities exist for men who have missed their chance early in life to secure instruction in correspondence schools and other similar institutions; yet in the very next sentence one reads that young men who can afford the time to study engineering "in the proper manner" have no place in these schools. It is a very serious matter to advise young men to get engineering education in second-rate schools, for if the engineering profession is to be improved, and if there are to be fewer structures falling down in the future, the results will have to be accomplished only by men having thorough training in the fundamentals. The author apparently thinks that our leading technical schools are doing good work and that they constitute the proper means for study. If this be the case, why recommend poor substitutes?

It is difficult to agree with the loose statements that "bridge engineering is practically a distinct profession" and "structural engineering is also a distinct profession." One might as well say that physicians who treat the eye constitute one profession and those who treat the ear another, which is absurd. Certainly bridge and structural engineering are not distinct professions; simply divisions of a large one.

In the first chapter, which is largely devoted to defining the engineer, the two following separate statements appear, indicating the carelessness with which the book has been prepared: "The modern engineer must have a college training or something that is equivalent." "If anything is a fault with the training given in the schools it is that many schools have paid entirely too much attention to outside criticism and the students are narrowly trained specialists, who have been cheated in their unfortunate attempt to get a proper education."

On the other hand, there are some things in the book which would be profitable reading for young men. Advice to acquire industrious habits in college because of the effect on after life is good, and many young men in colleges today would do well to act upon it.

After reading the book one doubts whether the author does or does not believe that engineering is a good vocation to follow and whether or not preliminary training should be taken in the technical schools. The book rather leads one to conclude that some absurd views regarding education recently emanating from Chicago have been somewhat contagious.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. X — New York, April, 1912. — No. 4

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

J. W. Richards, Ph.D., President.
James H. McGraw, Vice-President.
Curtis E. Whittlesey, Treasurer. E. F. Roeber, Secretary.
239 West 39th Street, New York.
Telephone Calls, 4700 Bryant.

Western Office, 421 Boston Bldg., Denver, Colo.
European Office, Hastings House, Norfolk St., Strand, London, Eng.

E. F. Roeber, Ph.D., Editor.
H. C. Parmelee, Western Editor.

J. M. Muir, Manager.

Yearly subscription price for United States, Mexico and United States dependencies, $2.00; for all other countries, $2.50 (European exchange, 10 shillings, 10 marks, 12.50 francs.)

Copyright, 1912, by the Electrochemical Publishing Company.

Entered as Second-Class Matter at the Post Office at New York, N. Y., under the Act of Congress, March 3, 1879.

New York, April, 1912.

The Patent Situation.

The legal importance of the much discussed U. S. Supreme Court decision in the Dick Co. case rests in the fact that it authoritatively fixes the extent of the monopoly guaranteed by a patent as absolute. A patent monopoly is guaranteed by the Constitution, but the extent of this monopoly, not being fixed by statute law, has been somewhat indefinite in the past, as is shown by the discrepancy between different lower-court decisions. Now this uncertainty is ended.

There is, however, a very practical side to this question. While reserving a discussion of this for a future occasion, this one point we want to make here, namely that in most discussions of the patent situation, two things are usually mixed up—the patent law and its working in practice or enforcement. We believe that the American patent law as law is pretty good and perhaps the best in the world, but that its practical operation, its enforcement, is about as poor as it can be, as under existing conditions the guaranteed protection can be enforced by an individual inventor only if he is backed by immense wealth.

The patent situation will be a national issue in a very few years. As its solution will have to be found by a "small representative part" of the whole people, engineers should make up their mind now that they are rightfully among those most concerned and should be represented. There is a hopeful awakening to the seriousness of the situation especially in chemical circles. When reasonable people begin to think over a thing and make up their mind what they want, they generally get it.

Concentration by Flotation.

Possibilities for improvement in concentration are to be found in the use of machines and methods which are only accessory to the well recognized and accepted practice of the day. Processes which are heralded as "revolutionary" are apt to receive scant consideration, but when a new proposal is made and its possible field of usefulness carefully outlined it is likely to be investigated. The flotation of dry crushed ore, described elsewhere in this issue, is such an accessory process, and doubtless will find special application in conjunction with standard methods of concentration.

The tendency of some sulphide minerals to float, unassisted by mixture with oil and acid, or the use of a vacuum, is not a newly discovered phenomenon. The relation of these substances to the surface tension of water is such that particles as large as eight or ten-mesh in size, which have been freshly crushed in the dry state, may be deposited on the surface of water without overcoming the tension of its surficial film. Indeed wetted particles of minerals may be exposed to the air and then delivered onto the surface of water without sinking. This latter phenomenon has been noticed many times on con-

centrating tables when treating certain minerals which show strongly the tendency to float. Such mineral usually is lost, and in some extreme cases it has been found useless to attempt concentration because the loss due to floating mineral was prohibitive.

We may consider, for example, the concentration of tetrahedrite carrying silver. This mineral is exceedingly friable, and the loss in ordinary concentration is sometimes very great. Resort may be had to the best systems of slime concentration, but even then the recovery is very imperfect. On the other hand, tetrahedrite shows a marked tendency to float on water, and so a way is opened to improve concentration by flotation. The freshly crushed ore may be treated by flotation first, and the fine floating concentrate recovered before it enters the mill system. Thus that portion of the ore which ordinarily is most difficult to recover, is at once saved, and the balance may be treated in the usual manner. An instance recently came to our notice where the use of flotation as an accessory to the regular practice permitted the profitable operation of a mine and mill which hitherto had been unprofitable.

Publicity in Nevada.

Perhaps no mining state has had more intimate experience with booms than Nevada. The Comstock days are only a matter of history to many of us, but the more recent excitement caused by the discovery of Goldfield is still fresh in the mind of anyone familiar with the mining industry. Mining promotion during the Goldfield boom required only a vivid imagination, a good press agent and the usual supply of printed and engraved paper. Fortified with these, the fiscal agent opened an office in an eastern city and employed an officer to keep the people in line while they besieged his office for the purpose of buying stock. The ownership of a mining claim, or the expenditure of real money in development was not considered necessary by the wild-cat companies which did Nevada so much harm during the Goldfield boom. It has been estimated that $30,000,000 would represent a conservative estimate of the cost of that boom.

Having suffered this affliction, Nevada determined on a cure which would be effective for all time, and the result is that mining and milling companies operating in that state are obliged to make public the important details of their work. The state levies a bullion tax on the output of all mines, and the amount is determined from the sworn statements of operation made by company officers. These statements, which include a report of tonnage mined and treated, its value and the expense incurred in those operations, are made public by the state bullion tax collector, so that all concerned in the property may know whether it is in operation and to what extent. The last statement issued contains authentic data on sixty-one companies and forms an admirable publicity report. There is one desirable thing the state cannot do, however, and that is to compel the public to read the statement and inform itself before investing its money.

Motion Study in Mill and Laboratory.

Inquiry among western technical men reveals a commendable tendency to apply the principles of scientific management to metallurgical works and laboratories. This kind of investigation has been developed most highly, and with gratifying results, in eastern industrial plants; but there is reason to believe that the idea has taken root in the field of metallurgy and will continue to develop until that branch of scientific industry has been greatly benefited.

Quite naturally the idea is being applied first to those operations which are routine in their nature, consisting of a number of separate motions or operations repeated many times throughout the period of labor. Shoveling, tramming and wheeling come under this head, as also do the operations of loading and dumping cars on aerial tramways. The different elements of such work can be plotted and presented to the mind graphically, and by studying the results it will be possible to see where time can be saved or capacity increased without hardship to the laborer and possibly to his advantage. Standards can thus be established to serve as a basis of labor and wage, and adjustments can be made whereby greater efficiency will gain extra remuneration.

Some of the routine work of the laboratory also can be standardized to the great advantage of the chemist. The arrangement of the laboratory and the use of appropriate apparatus are important factors in reducing the number of motions or steps necessary to do a day's work. A standard of efficiency can be established, based on the accuracy of the work as gauged by the number of determinations necessary to be repeated, or the percentage of umpires won and lost. In this way a healthy rivalry can be produced and the standard of efficiency kept high.

In order successfully to carry out these ideas there must be broadminded management, definite organization and perfect cooperation. The benefit of the laborer must be kept in mind in order that the company ultimately may reap the results of his interest and improved work. As yet the application of the idea is limited in metallurgical work, but those who have endeavored to apply it are enthusiastic over the results obtained and see great possibilities in further application. We join them in urging upon technical men everywhere a general study of the principles of scientific management and the publication of the results obtained in order that the whole industry may prosper and make progress.

The Steel Corporation's Report.

The United States Steel Corporation's annual report, issued under date of March 19, 1912, and covering the calendar year 1911, contains as usual a full statement of the corporation's operations in the year. An approximate statement of the year's earnings has been available since the publication of the statement for the fourth quarter, but the final figures, as usual, contain the result of various minor adjustments made after the close of the year.

The corporation began business April 1, 1901, its earnings in the remaining nine months of that year being $84,787,597, but no statement of production in the period was made. For subsequent years we present below a table showing (1) total earnings, being the earnings after provision for ordinary maintenance and repairs and payment of interest on subsidiary company bonds, but before allowances are made for sinking funds against subsidiary company bonds, or the regular allowance for depreciation, interest and sinking funds against the

steel corporation bonds, etc.; (2) the steel products for sale, comprising material in the form in which it passed to customers of the steel corporation, these totals, according to the practice of the steel corporation, being made up of gross tons for all products, except that wire and products of wire and finished structural work are represented in net tons; (3) our computation of the average earnings per ton:

	Total earnings.	Steel products for sale	Average per ton.
1902.....	133,308,764	8,033,556	$16.59
1903.....	109,171,152	7,458,879	14.64
1904.....	73,176,522	6,792,780	10.77
1905.....	110,787,058	9,226,386	12.08
1906.....	156,624,273	10,578,433	14.81
1907.....	160,964,674	10,376,742	15.51
1908.....	91,847,711	6,206,932	14.80
1909.....	131,401,414	9,850,660	13.34
1910.....	141,054,755	10,733,005	13.14
1911.....	104,305,466	9,476,248	11.07

What is particularly impressive about the Steel Corporation's operations is that the average earnings per ton vary less than would be expected from observation of the vicissitudes in the trade. When prices are high and mills are operating full and therefore presumably at greatest efficiency the earnings per ton do not rise, and when prices are low and production is far below capacity the earnings per ton do not fall as much as would be expected. For example, the years 1906 and 1907 were years of full operation, except for a sharp decrease in November and December of 1907, and earnings averaged $15.16 per ton in the two years. In 1911 prices were $5 to $7 per ton lower and production 10 per cent less, yet earnings averaged only $3 per ton less.

It must be remembered, of course, that what are loosely called the "high fixed charges" of the Steel Corporation are quite largely charges which are paid after these "total earnings" are ascertained, and the factor of decreased operations affects the balance of earnings available for common stock dividends much more than it does the so-called "total earnings." The corporation's fixed expense, paid before the "total earnings" are reported, amounted in 1911 to about $34,000,000, this being made up of somewhat more than $16,000,000 of administrative and other general expense, a trifle less than $10,000,000 of taxes and about $8,000,000 interest on obligations of subsidiary companies. These items vary but little from year to year, whether production is high or low, varying well inside the limits of $3 and $6 per ton in the years of maximum and minimum tonnage respectively.

After meeting the requirements of the depreciation and extraordinary replacement funds, the bond sinking funds and paying interest on bonds, 7 per cent on the preferred stock and 5 per cent on the common stock, there was left as the 1911 contribution to surplus the sum of $4,665,495, which is less than 50 cents per ton of the 1911 production. During the year there was a decline in the average selling prices of finished steel products, except rails, of about $5 per ton, so that obviously the Corporation was very close to the line in the matter of earning its regular dividends on the common stock. This dividend amounted to about $2.70 per ton of output.

The Corporation to-day is operating to better advantage than in 1911. Prices are lower, it is true. They are not an average of $1 per ton higher than the minimum level of 1911, and they are nearly $2 a ton lower than the average level of that year. On the other hand, production is at a much better gait. The United States as a whole is making pig iron at the rate of about 27,000,000 tons per annum, the actual production in 1911 having been only 23,649,344 tons, while the Steel Corporation is operating at between 85 and 90 per cent of its full capacity against an average of only 67 per cent in 1911, as we learn from a statement in the annual report.

The Steel Corporation's exports in 1911 of rolled steel and other finished products amounted to 1,719,272 tons. The country's total exports of all such products amounted to 1,955,924 tons, indicating that the corporation conducted 88 per cent of the export business in these lines. Its exports of pig iron and scrap amounted to 26,728 tons, the total exports of the country being 198,717 tons. There were also exports of bar iron and of cast radiators and house heating boilers, essentially tonnage products of the iron and steel industry, to which the corporation did not contribute.

The operations at the Gary plant were of particular interest. Production of the Indiana Steel Company in 1911 was as follows, in tons:

By-product coke.....	811,804
Pig iron.....	707,273
Steel ingots.....	1,036,545
Rails	281,980
Other rolled steel.....	469,360
Total rolled steel.....	751,340

There are eight blast furnaces at Gary, rated at 1,200,000 tons per annum, the 1911 output thus being 59 per cent of the rated capacity. While the first battery of by-product ovens was not put in operation until April 12, 1911, four other batteries coming in at later dates in the year, it is probable that the by-product plant made nearly all the coke required by the blast furnaces in 1911, blast furnace operations at Gary having been light early in the year. The total output of rolled steel only slightly exceeded the production of pig iron, and it may be inferred that little outside scrap was used. The production of rolled steel was 72.5 per cent and the production of pig iron 68.2 per cent of the steel ingot production, but of course these comparisons throw no light upon the average proportions of scrap and pig iron charged into the open-hearth furnaces, even an approximation to the proportion being impossible from these data.

The report refers to the cancellation of the lease of the so-called James J. Hill or Great Northern ore properties, but makes no effort to suggest the reason which led to the cancellation. It is merely stated that "in accordance with an option reserved to the lessee to cancel the lease on Jan. 1, 1915, the Great Western Mining Company on Oct. 26, 1911, formally notified the lessors that the company elected to cancel the lease." It is not without interest to observe the coincidence of dates involved in this information and that conveyed in the succeeding paragraph of the report, which paragraph begins: "On Oct. 26, 1911, the United States Government filed a petition in the Circuit Court" against the Corporation under the act of July 2, 1890. The statement is made that it is the intention to mine sufficient ore prior to Jan. 1, 1915, to balance the royalty payments exacted under the terms of the lease, which involve a progressive annual minimum. This will make a total of 26,474,320 tons of ore to be shipped under the lease prior to its relinquishment, of which 7,832,137 tons was shipped up to Dec. 31, 1911.

Boston Meeting of the American Electrochemical Society.

The annual meeting of the American Electrochemical Society will be held in Boston, Mass., from April 18 to 20.

Meetings for the reading and discussion of papers will be held on Thursday morning, Friday morning and afternoon, and Saturday morning. One of the sessions will be held at Harvard University, the others at the Massachusetts Institute of Technology.

The sessions of Friday will be devoted to a symposium on electric conduction to which Messrs. W. C. Bray, C. J. Davisson, H. M. Goodwin, C. A. Kraus, S. C. Lind, S. J. Lloyd, D. McIntosh, H. N. McCoy, R. A. Millikan, T. G. Nutting, O. W. Richardson, and E. Weintraub will contribute papers. An illustrated lecture on conduction through gases will be delivered by Prof. Cross on Thursday evening before the smoker.

For the other professional sessions papers have been announced by Messrs. W. D. Bancroft, C. W. Bennett, R. Beutner, W. F. Bleecker, D. S. Cole, C. G. Fink, F. A. J. FitzGerald, C. Hambuechen, Carl Hering, A. R. Johnson and W. R. Woolrich, O. L. Kowalke, F. C. Mathers and O. R. Overman, W. Lash Miller, J. W. Richards, L. E. Saunders, W. Sykes, R. Turnbull, and J. R. Wilson.

There will be a smoker on Thursday night and a dinner on Friday night and on Thursday afternoon excursions, one to Worcester (Norton Company works and Steel Corporation electric-furnace plant), the other to the General Electric Works in Lynn, Hotel headquarters are at the Hotel Lenox.

The Iron and Steel Market.

On the whole, it may be said that a measurable improvement occurred in the iron and steel trade during March, but the improvement was disappointing, as throughout the first two months of the year a very noteworthy improvement was expected upon the approach of spring. Such improvement as has occurred has only been in spots, there being no semblance of sustained buying. For instance, the agricultural implement trade is normally expected to be placing heavy specifications at this time, while the current condition is that its specifications are light. Apparently the implement trade is deterred more by the political outlook than it is encouraged by the prospects of excellent crops.

The price situation in steel products is altogether unsatisfactory, in that there is no response to demand. The finished steel industry is really experiencing a heavy demand, sufficient to engage 80 or 85 per cent of existing capacity, against an average of less than 70 per cent during 1911, yet prices show no resistance, and for several commodities are absolutely the lowest on record. This last statement is true of shafting, railroad spikes, merchant pipe, boiler tubes and sheets. These products are selling at fully as low a level as last November, and in some cases at lower levels. At that general low point a number of products dropped to the lowest level on record. Others, which remained a trifle above their minimum in the historic low period of 1897-8, scored advances in December, but have lost portions of these advances.

The backbone of demand at this time is the steel car trade. A heavy buying movement started late in October and enabled the car shops to enter the present year with orders for more than 75,000 all-steel or steel underframed cars on their books. The program then adopted was to operate at between 50 and 60 per cent of capacity, which would meet the double desideratum of producing at a low cost and at the same time hold the operating organizations together. The shops have a total capacity of about 1000 all-steel or steel underframed cars per day, and in the first three months of the year have been producing at an average of not more than 500 cars a day. Since January 1 they have booked new orders to the extent of more than 20,000 cars, fully equal to their current output, and are now in the position of being able to operate at the present gait until almost the close of the year without any new business.

Pig iron is being produced at the rate of about 27,000,000 tons a year, against a capacity of about 34,000,000 tons, and 23,650,000 tons actually produced in 1911. The steel industry proper is operating at about 85 per cent of capacity.

The prospective suspension of mining in the anthracite and union bituminous coal districts March 31 has had the effect of creating a heavy demand for coal and advancing prices of both coal and coke. By the middle of the month Connellsville furnace coke for spot shipment commanded $2.10 at ovens, against $1.50 in November and an average of about $1.85 in January. A suspension of mining is certain, and is likely to affect both production and consumption of iron and steel, fully as much the latter as the former, so that the disturbance promises no good. Many by-product coke plants, which depend upon union-mined coal, will probably have their output materially reduced. The Connellsville region is non-union, but cannot increase its output materially.

Pig Iron.

Early in March a sharp burst of activity occurred in Bessemer pig iron in the central west, sales aggregating 120,000 tons in a few days, the United States Steel Corporation taking 30,000 tons, the Youngstown Sheet & Tube Company 80,000 tons, and the Republic Iron & Steel Company 10,000 tons. The general price was $14, valley, which had been the market, but the figure was slightly shaded in some of the transactions, and for 55,000 tons of the iron taken by the Youngstown Sheet & Tube Company ore was given in partial payment. The market immediately stiffened to $14.25, and at this figure half a dozen steel casting concerns bought from 1000 to 2500 tons each. Basic iron in the central west was also active. Several interests together absorbed the entire stock of warrant iron at Midland furnace, some 50,000 tons which had been an incubus on the market for a year, while furnaces also effected important sales, and the market advanced sharply, closing the month at $13, valley, for prompt and $13.25 to $13.50 for extended delivery. The low point had been $12.25, valley, in January. Southern iron steadily stiffened during the month, though without large transactions, and closed with $10.25, Birmingham, the minimum on nearby deliveries, and $10.50 demand for second quarter. In other markets the movement was limited, but the tendency is toward higher prices. Current quotations are: Foundry iron, $10.25 to $10.50, Birmingham; $14.75 to $15, Philadelphia; $13.75, Buffalo; $14, Chicago; $13.25, valley; Bessemer, $14.25, valley; basic, $13 to $13.50, valley, malleable, $13, valley.

Steel.

Inquiry has not been heavy for unfinished steel. Some sheet and tin mills have made desultory inquiries for second half sheet bars, without business resulting. As in other branches of the market, there is a wide range in the anxiety of the mills to sell, some being ready to cut prices while others do not quote at all. Minimum quotations are on the basis of about $19.50 for billets and $20 for sheet bars, but these figures are only approximate. Bessemer is scarce at Pittsburgh, but freely offered at Youngstown, while with open-hearth material the reverse is the case.

Finished Material.

Current prices, f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill except Colorado.

Plates, tank quality, 1.10 to 1.15; Chicago, 1.25 to 1.28 cents.

Shapes, 1.12½ to 1.15 cents.

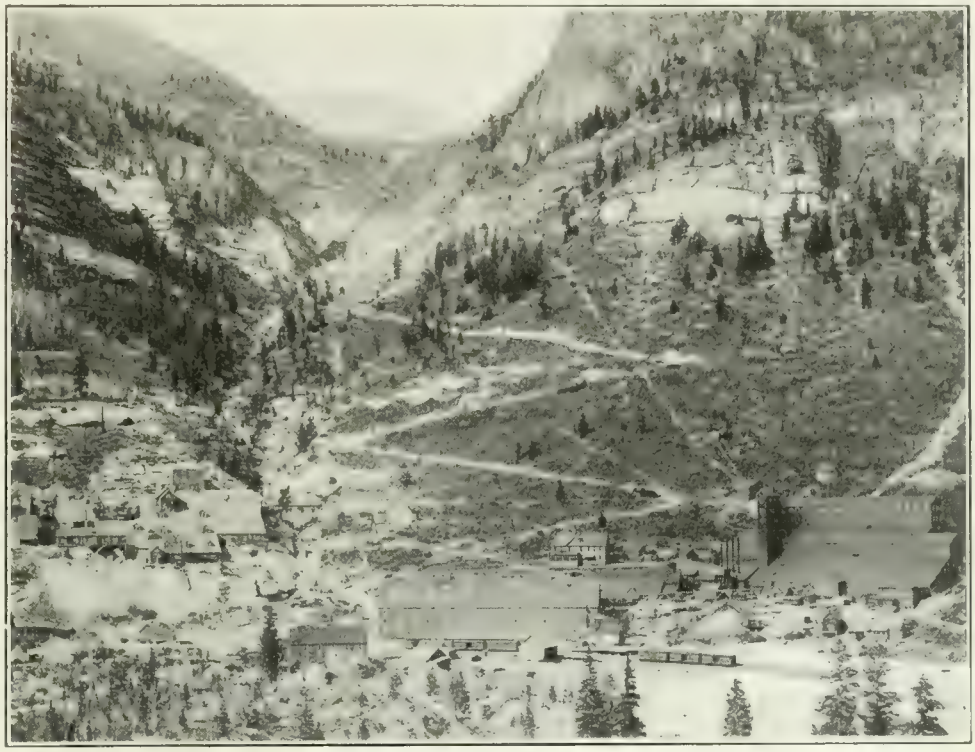
Steel bars, 1.10 cents; 1.25 cents, Chicago.

Iron bars, 1.25 cents, Pittsburgh; 1.22½ to 1.25 cents, Philadelphia; 1.15 to 1.20 cents, Chicago.

The Western Metallurgical Field.

Remodeling the Smuggler-Union Mill.

Important alterations are under way at the milling plants of the Smuggler-Union Mining Company, at Telluride, Col., which, when completed, will result in very materially improving the system of ore treatment. The mills owned by this company are shown in the accompanying illustration. The two stamp-amalgamation-concentration mills are shown at the right and left of the picture, with the cyanide plant in the center. The stamp mill at the left is partly in operation by lessees, and the other stamp mill and cyanide plant are operated by the company. It is in the latter two plants that the changes are being made.



SMUGGLER-UNION MILL, TELLURIDE, COLO.

The stamp mill is being remodeled principally as regards concentration. Formerly bumping tables were used; but these have been removed and replaced by Wilfley tables. The flow of ore in the remodeled mill will be about as follows: The stamps will crush through 16-mesh screen and deliver the pulp onto amalgamating plates. Following the plates are Pierce riffles, and from these the ore will flow to a hydraulic classifier. The products from the coarse spigots will be treated on Wilfley tables, while the classifier overflow will be thickened in Callow cones and concentrated on vanners. A feature of the treatment will be the use of Hardinge conical mills for regrinding table middling.

The tailings from the stamp mill will be sent to the cyanide plant for further treatment. The overflow of the Callow cones and the vanner tailing will be combined into one product, all of which is fine enough for agitation in cyanide solution. The tailing from the Wilfley tables will contain sand and slime and will have to be classified.

Formerly the only cyanide treatment consisted in leaching sand tailing. The stamp mill tailing was charged into tanks, the slime being allowed to overflow and pass to the creek. The sand charge was then leached with cyanide solution. The new system will retain the old sand leaching plant, but will include, in addition, a modern slime agitation-filtration plant. The Wilfley tailing will be classified into sand and slime by means of Akins classifiers. The sand will be treated as before, but the extraction should be materially improved and the time of treatment lessened, owing to the complete removal of the slime. The classified slime will be combined with the vanner slime, and collected in 40-ft. tanks fitted with Dorr continuous slime thickeners.

An interesting problem was presented in designing the slime plant. The pulp is sent to the cyanide plant in a very dilute condition, possibly 25 or 30 parts of water to 1 of dry slime. This necessitated getting rid of a large quantity of water as completely as possible, for in the subsequent continuous cyanide treatment it would be necessary to throw away as much barren cyanide solution as might enter the system with the slime pulp. Hence, thickening and filtration were necessary preliminary processes before cyanide solution could be added.

Four of the old sand leaching tanks have been converted into Dorr thickeners. Three of these will be used in dewatering the original slime pulp, and the fourth as a continuous decanter of cyanide solution from the treated pulp. The thickened pulp will be sent to the dewatering filters, which are of the continuous revolving-drum type known as the Portland. As the dewatered slime is discharged from the filters it is mixed with cyanide solution and sent into the agitation system.

Four Pachuca tanks have been erected, adapted to either intermittent or continuous agitation. The tanks are 15 ft. diameter and 45 ft. high, with 60-deg. cone bottoms. After agitation, the pulp will be pumped to the fourth Dorr thickener, the overflow of which will go to the zinc boxes. The thickened pulp will be pumped to an equalizing tank which will feed other Portland filters, where the final recovery of cyanide solution will be made.

Thus the process will consist in thickening and filtering original slime pulp, agitating in cyanide solution, followed by further thickening and filtration of treated pulp. The system presents an interesting experiment, for by first crushing and concentrating in water, and then filtering the tailing before cyanidation an excellent opportunity will be afforded to wash cyanicides out of the pulp, and the idea may prove of value to other San Juan properties producing ore not directly amenable to cyanidation.

The present system of zinc box precipitation will be retained, and the "waste' box solution will be discarded in sufficient quantity to counterbalance the water introduced into the system with the dewatered slime pulp.

Company Reports.

The Florence-Goldfield Mining Company, about which there has been so much speculation since the loss of the mill by fire in December last, has issued a report covering the last calendar year. It appears that the revenue from milling operations in January, 1911, was less than for several months previous, owing to reduced grade of the ore, and that this general condition prevailed until August, when the value of the ore fell so low that it was a question whether it would be worth milling. This continued through October, and in November drastic measures were taken to raise the grade of ore by close sorting and by taking some ore from several dumps. In the

latter part of November the mine began to make a better showing, and it was believed that the improvement would be permanent.

On the evening of Dec. 2, however, a fire of unknown origin started in the boiler room of the mill and completely destroyed the plant. The value of the property destroyed, after taking care of depreciation, which always has been the company's policy, stood on the books Dec. 1, 1911, at $295,980. The insurance on the same was $83,500, leaving a net loss of $212,480. The destruction of the mill has so crippled the company that it is deemed best to spend every effort on mine development before reconstructing the mill.

During the year 1911 there was treated a total of 48,847 dry tons of ore, of gross value of $298,193, yielding bullion to the value of $251,561, representing a recovery of 83.96 per cent. No concentrate was made, as a system of local treatment was devised which permitted extraction by amalgamation and cyanidation.

The Giroux Consolidated Mines Company has issued its annual report for the last calendar year, covering operations at the properties at Kimberly, Nev. In addition to detailed reports on mine development, the report contains announcement of the company's arrangement for ore treatment.

There is now fully developed in the Morris-Bunker Hill mine 4,010,000 tons of porphyry ore of an average assay value of 2.14 per cent copper. There is also a large quantity, probably several million tons, of partly developed ore of at least an average assay value of 1.73 per cent copper. In the whole, it is estimated that there is a total tonnage of fully and partly developed ore amounting to 10,291,000 tons assaying 2 per cent copper; 6,599,000 tons fully and partly developed ore assaying 1.65 per cent copper, and several million tons of lower grade ore carrying at least 1 per cent copper. It is estimated that the precious metal value of these ores will amount to not less than 1 cent per pound of refined copper.

The company has a concentrating plant of 500 tons capacity at Kimberly, but it has not been operated since 1909 on account of a shortage of water. In view of the ample water supply developed in the Alpha shaft, sufficient to supply a concentrating plant of several times the capacity of the present unit, it was thought it might be advisable to operate the concentrator instead of selling the ore. Investigation, however, showed that at least eight months' time would be required to build additions to plant in order to bring it up to 1000 or 1200 tons daily capacity, and in the meantime it was thought wise to bring the mine to the producing stage. Consequently the company entered into a contract with the Steptoe Valley Company (Nevada Con) for the treatment of from 900 to 1200 tons daily. The rates and charges are such that the cost of producing and marketing refined copper will be about 9.5 cents per pound. The contract commences May 1, 1912, and may be terminated by either party on one year's notice.

The Temiskaming Mining Company has issued its fifth annual report covering the calendar year 1911. Owing to a change in the formation encountered in the mine, it is believed by the general manager that the life of the mine has been materially shortened. As a consequence of this condition the company has purchased a controlling interest in the North Dome property at Porcupine and expects to continue as a profit-paying company. The Temiskaming mine at Cobalt still contains reserves, but it is difficult to estimate them with accuracy.

During 1911 the mine produced 24,783 tons of ore at a cost of $6.85 per ton, being 46 cents less than for the previous year. Hand sorting played an important part in the production, 6559 tons being handled, producing 139 tons of shipping grade, 6058 tons of mill ore and 362 tons of waste. The total cost of this work, including bagging and shipping the high-grade ore, was 41 cents per ton, being 14 cents per ton less than last year. The assay value of the shipping grade ore was 4801.4 oz. silver per ton. The highest grade shipment contained 6414 oz. silver per ton. The average price received for silver was 53.9 cents per ounce, as compared with 54.3 cents last year. No payment was made in 1911 for cobalt, nickel or arsenic; on the other hand, penalties were exacted for arsenic in some cases.

The mill treated 34,720 tons of ore containing 685,120 oz. silver, producing 770 tons of concentrate containing 546,743 oz. silver. This gives a concentration of about 45:1 and a recovery of 80 per cent. The stamp duty was 3.13 tons per 24 hours. The total milling cost was $3 per ton, being 86 cents less than last year. This cost is divided as follows: Mill, $1.44; crushing, 0.30; ore house, 0.08; aerial transportation, 0.07; laboratory, 0.09; smelting, 1.02. Total mine and mill cost, $10.57 per ton.

The Arizona Copper Company, Ltd., announces in its annual report under date of Feb. 23, 1912, that the proposal for the erection of new reduction works and power plant has been unanimously approved, and Consulting Engineer Ricketts has been instructed to proceed with detailed plans and other preliminary work. Early in January a contract for the supply and erection of steel work was accepted. Ground was broken on Jan. 15.

Ray Consolidated Copper Company.—In a report covering the fourth quarter of 1911 it is announced that the rate of production during the period was about 100,000 tons per month. It is estimated that at the end of March the production would reach 4500 tons per day. The average grade of ore for the quarter was slightly less than 1.75 per cent. It is expected that the grade will improve during the first quarter of 1912 so that it will average 2 per cent copper. The cost of mining has been about 76 cents per ton and of milling about 57 cents.

The fifth section of the concentrator was constructed with certain alterations and improvements resulting from the operation of the first four sections, and the first four have been similarly altered. No further sections will be put in operation until a capacity greater than 5000 tons per day is required. The rate of recovery has averaged about 70 per cent. Since the middle of February concentrates have been delivered to the new A. S. & R. Company smelter at Hayden.

The Chino Copper Company has issued its first quarterly report covering the fourth quarter of 1911. Since Jan. 1 two sections of the mill have been in operation, treating about 800 tons each per day. The ore is partly oxidized and the recovery is not as good as it will be later on—clean sulphide ore. The recovery has been at the rate of 30 lb. of copper per ton at a cost of 8.3 cents per pound. The completed plant of five sections should be in operation in July.

CORRESPONDENCE.

Pinch-Effect Furnace.

To the Editor of Metallurgical and Chemical Engineering:

Sir: Concerning the new type of electric furnace in which the force developed by the pinch effect is used for circulating the metal in the resistors (see this journal, vol. IX, page 277 and 371), the belief has been expressed by critics both in this country and abroad, that there would be a serious wear on the refractory walls of the holes in which the heat is generated, caused by the rapid flow of heated metal through them.

Will you therefore permit me to say in your journal, in justice to that furnace, that trials were recently made to determine the extent of this much talked-of wearing away.

In a furnace which had been run daily with bronze, the last charge was allowed to freeze and the furnace was then demolished when cold so as to expose the frozen cores in these holes. It was found impossible to detect any increase in size. The surface of the refractory material (a special form of magnesite) forming the walls of these holes, was found to be clean, even and smooth, as though it had been sand-papered.

A similar test was then made with a steel furnace; it had been running daily, not only on steels but also on some steel alloys, the heating of some of the charges having been very

intense. Again no measurable wear could be detected. On the contrary there seemed to be even a slight diminution of the cross section of the holes. This was apparently due to a hard, smooth, clean, black coating which forms on the surfaces of the holes, presumably from the oxides and other impurities in the iron combining with the magnesite.

Hence the fear about this much talked-of wear seems to have been premature and needless. But even if there should be some wear, as there may be in course of time, it can be taken care of to some extent by regulating the transformer to give a greater current at a lower voltage; such regulation should be provided in any case on account of the varying resistivities of the metals due to different compositions and different temperatures. Should it exceed the limits of the transformer it can be taken care of by lengthening the holes by tamping a layer of refractory material over the bottom, as is frequently done in repairing steel furnaces. If the ratio of length to section be maintained the same, the heat produced will remain the same. And as the pinch force would generally be more than ample, a slight reduction in this force due to an enlarged cross section will be of no importance.

Another unexpected result is that the expansion and contraction of the metal and the lining for short holes seems to be so nearly the same that no rupture of the core takes place in cooling down over night; the furnaces were started repeatedly in the mornings on the remnant of the frozen charge of the day before.

Philadelphia, Pa. CARL HERING

The Crystallization of Carbon by Artificial Means.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—The artificial production of diamond has doubtless been attempted many times, in a somewhat indifferent manner, but apparently the effort has never been followed up with any degree of persistence, and certainly not to a successful issue in a commercial sense within the knowledge of the public. Our available information on the subject is limited to the published accounts of certain experiments made by a few noted chemists some years ago; and what may have been done by others the result of whose experience has never been disclosed can only be conjectured.

The reports of hidden secrets and stories of wonderful discoveries in this direction which have now and then become current have heretofore invariably been discredited, but manufacturing chemists are now producing many substances of natural origin by artificial means; and a diamond even of the most perfect formation is composed solely of one ingredient, if we may use the term, and that constituent is a simple element which is otherwise of the commonest occurrence.

When these facts are considered in view of the many achievements of modern science, and the marvelous feats of applied chemistry which have revolutionized the industries of the world, it is strange, indeed, that the artificial production of a material now so excessively costly and which might otherwise be of great use in the mechanical arts has been so long delayed; and so far from being incredible, the news of its attainment would in reality be less wonderful than the apparent fact that it has not already been accomplished.

If it is feasible to undertake the construction by synthetic combination of a complex substance of vegetable origin, and of such peculiar nature and specific properties as india rubber, it is surely within the province of industrial chemistry to attempt the formation of a simple mineral by the transposition of an element from the amorphous to the crystalline form.

So far, however, as published accounts go, it would seem that the experiments hitherto tried for this purpose have been performed upon a very small scale, entirely inadequate for the production of decisive results, and by methods which are only partly capable of establishing the desired conditions. The means employed being some simple and expedient quickly devised and always abandoned without further attempt. And yet it is an admitted fact that a number of these trials have produced traces of diamond material, very small particles, it is true, merely minute specks, but crystallized carbon in character, and this is diamond.

Moissan, in France in 1893, formed a saturated solution of carbon by heating melted iron to a temperature of 3000 deg. F. and adding all the carbon the molten metal would take, and then plunged the body of seething liquid into water; and Chroustchoff performed a similar experiment, using silver instead of iron. In both instances after the metals were dissolved away by an acid there remained at the bottom of the containing vessel a gritty black powder which proved to be graphite mixed with minute particles of crystallized carbon.

In these experiments advantage is taken of the fact that iron or silver at their boiling points, and also several other metals, notably tungsten and manganese when highly heated, will assimilate as much as 6 per cent of carbon, completely dissolving the element but precipitating it more or less upon a reduction of temperature; and it was Moissan's idea that the pressure produced by the contraction of sudden cooling would cause the disengaged carbon to crystallize.

Friedel, about the same time, heated to a temperature much below redness, in a closed vessel, a mixture of highly carbureted iron and sulphur, forming sulphide of iron, and as in the cases previously noted, the carbon was left in the form of a dust containing particles of extreme hardness and exhibiting the properties of diamond.

The experiment of Moissan is generally regarded as a demonstration of the theory that the diamonds of Nature were formed from melted and compressed carbon; that is, from carbon liberated and liquefied by some reaction at a very high temperature within the interior of the earth or some portion of its crust, and cooled under an intense pressure caused by the contraction of a mass of solidified mineral matter in which the body of fused carbon was embedded. But the analogy is very imperfect for the reason that carbon derived from its solution in molten iron is deposited at a temperature below its point of perfect fusion, and is for the most part precipitated (in consequence of this fact) in an amorphous condition. There evidently was, however, a partial fusion of some part of the disengaged carbon, and to this circumstance may be attributed the existence of the minute crystals found in the residium.

In Friedel's experiment, however, there was no pressure and practically no heat, as the reaction was accomplished at a temperature but little above the melting point of sulphur, and we might be misled into the belief that the crystallization observed in this case was effected without the aid of heat or pressure, but the conclusion would be erroneous, as the crystals found were previously formed in the carbonized iron and the action of the sulphur was practically no more than that of a solvent, removing the iron by combination and leaving the carbon unchanged.

In estimating the practical value of these experiments for the purpose of further development it may be said that while they were conceived in recognition of a theory which is probably correct, they do not, as we have already seen, embody the conditions demanded by that theory, and can not therefore be made the basis of a successful process.

Professor Hanney as long ago as 1880 also experimented upon this problem by heating a hydrocarbon liquid in contact with magnesium in a closed iron tube, but the tubes usually burst, and after a number of vexatious trials the effort was abandoned. The trouble was caused by the fact that the heat applied to the outside of the tubes weakened the metal to the point of rupture long before the required temperature was even approached. It was Hanney's conclusion that the diamond could only be formed at an extremely high temperature and under an almost incalculable degree of pressure. Such conditions as might be imagined to exist within the impenetrable walls of the earth's crust at a depth of 2 miles below the surface. But it is highly probable that if a body of pure car-

bon fused and thoroughly liquified by a sufficiently high temperature could be maintained without evaporation complete crystallization would ensue as the element cooled.

It is impossible, however, to secure such conditions in the open air by any means whatever, as the melting point of carbon is away above its temperature of vaporization, and were the requisite degree of heat applied in this way complete evaporation would take place without fusion, and just what condition would be assumed by the condensed vapor is somewhat uncertain, but we may fairly conclude that it would be some form of the inevitable black powder and not diamond.

We know, however, that evaporation is retarded by pressure and that the boiling point of a liquid is partly dependent upon the pressure to which it is submitted; and it is, therefore, evident that if we could melt a body of carbon under a sufficient pressure to raise the boiling point above the temperature of fusion we would have secured the conditions which, there is good reason to believe, would result in the formation of diamond.

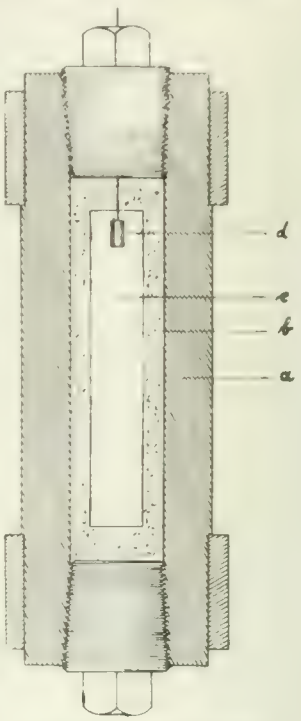
The melting point of carbon is said to have been estimated by Sir William Crookes at 2400 deg. C., and its boiling point at 3500; and that eminent authority is further quoted as saying, in effect, that at the melting temperature a pressure of 2551 lb. per square inch would be likely to promote crystallization. But these points can be definitely determined only by further experiment.

In regard to the available means of producing a temperature so high as the case requires, the electric arc at its highest power is incapable of melting carbon and is, therefore, out of the question, as is also the well-known thermit reaction as usually employed in an unconfined space, but Sir Andrew Noble is believed to have produced a temperature of 52000 deg. C. and a pressure of 50 tons per square inch by the explosion of picric acid in a closed steel tube, and here at least is a possible solution of the problem.

But if this statement is true it is highly probable that there are also many other explosive substances which are capable when ignited in a confined space of producing an equally high degree of heat. Possibly if the thermit reaction were conducted in this way, that is, burned in a closed steel tube under the pressure caused by the expansion of its own products, or of some added material, the temperature would reach a point equal to or even beyond that produced by the experiment of Noble. The pressure generated in this way, however, would be in no wise equal to that of the picric acid explosion, but it might reach 5 tons per square inch, and this should prevent the volatilization of a body of carbon embedded within the ignited mass and fused by the heat of the reaction.

In the accompanying drawing a mechanism proposed for these experiments is shown in the sectional view, in which *a* is a cylinder of vanadium steel 26 in. in length with a bore of 4 in. and having an outside diameter of 8 in. Taper threaded steel plugs are fitted to the ends. The side walls of the cylinder as well as the ends are lined with graphite or some form of carbon, 1 in. thick in the sides and 2 in. thick at the ends. This leaves a circular cavity 2 in. in diameter and 12. in long for the reception of the charge. The detonator may be a fulminate cap, the insulated terminals of which pass out through a very small hole in the center of one of the end plugs, as shown in the figure, in which *b* is the carbon lining, *c* the charge, and *d* the detonator.

The object of the lining is twofold. It forms an insulation against the immediate escape of the heat and thereby promotes a higher temperature and a more prolonged effect, and also protects the walls of the cylinder and the ends of the plugs, and as a further precaution against the weakening effect of the heat upon the material of the cylinder the device when used is to be exploded under water. The charge may consist of picric acid, or of thermit powder mixed with, say, 10 per cent of graphite or lampblack. In the experiment of Noble there was evidently a production of free carbon resulting from the disassociation of the elements of the explosive; but there was no more than a trace of crystallization in that case by reason partly of the small size of the apparatus used. The heat being dissipated so quickly that there was not sufficient time for the carbon fused in an atomized condition to collect in an integral body. But if these materials should fail in this case also, there is a very large number of other carbon-bearing substances which are capable of disassociation under similar conditions and which might yield the desired result. The following is a list of a few combinations that are known to be of this nature in a greater or less degree, and from which a successful operation might be secured:



SUGGESTED ARRANGEMENT

Carbide of calcium is decomposed at a red heat in the presence of nitrogen, the latter uniting with the calcium and releasing the carbon.

Hydrocarbon liquids are decomposed by chlorine, a portion of which combines with the hydrogen and another portion with part of the carbon, leaving the remainder of the carbon free.

When carbon bisulphide is heated in contact with copper the metal appropriates the sulphur and throws down the disengaged carbon. Doubtless some other metals would have a similar effect, and conditions might be devised wherein a reaction of this kind would become so energetic as to assume the form of a violent explosion, evolving heat and generating sufficient pressure to crystallize the deposed carbon.

Phosphorus is also said to be capable of decomposing the bisulphide, and it would be easy to arrange means for conducting this reaction safely under a very high pressure and a considerable degree of heat.

Acetylene is a hydrocompound surcharged with carbon and easily decomposed, but when submitted to compression is of such a violent nature that its manipulation is extremely hazardous, and no experiment should ever be undertaken with it unless the circumstances are known to be such that no harm can come to the operator in the event of a premature explosion. If, however, the cylinder shown in the drawing could be filled with this gas previously liquified by cold, and then plugged up perfectly tight and placed in a body of water, the imprisoned liquid would explode spontaneously when its temperature reached the normal condition of the atmosphere or of the water in which the containing cylinder was immersed, and the nascent carbon thus disassociated would be placed under such extreme conditions of heat and pressure that crystallization hight fairly be expected to result; that is, if the assumed theory be correct, and the process of Nature in the formation of diamond can possibly be duplicated by any means within the reach of art.

We might go on much further in this way enumerating combinations and chemical reactions possibly capable under the conditions proposed of resulting in the formation of diamond, but it is hoped that enough has been said to at least suggest a successful experiment to those who have the means and mechanical facilities, and that such a trial may subsequently lead to the development of a process for the production of crystallized carbon upon a commercial scale.

Oroville, Cal. S. M. HOWELL

The American Chemical Industries.

To the Tariff Board we are indebted for a very interesting volume on some of the chemical industries of this country. It is entitled **"Chemicals, Oils, and Paints. Glossary on Schedule A.** An analysis by paragraphs of Schedule A of the Tariff Act of August 5, 1909, and a statistical survey of the industries affected thereby, with a comparison of tariff laws since 1883. Prepared under the direction of the Tariff Board, transmitted to the Ways and Means Committee of the House of Representatives, February 7, 1912" (274 pages).

Being a congressional document submitted under the authority of the Tariff Board, the name of the author is not stated in the volume. However, at this place there is no reason to omit it, but every reason to congratulate Dr. Bernard Herstein for having produced a very interesting volume.

"Up to the year 1883 chemicals were distributed among the various tariff subdivisions of the respective tariff acts, although classified principally under 'Sundries.' The tariff policy pursued toward chemicals varied, of course, with the vicissitudes of changing political opinion and practically every one of the seventy-odd tariff acts enacted in the United States since 1789 affected in some way one or another commodity properly regarded as chemical. With their increasing commercial or industrial importance more attention was bestowed upon these articles, and the list of special items increases continually as time passes. A comparison of the different tariff acts with reference to the time of the first introduction of, and the subsequent changes in, the rates of duty imposed upon the various chemicals would furnish a great deal of interesting historical material as to the development of the chemical industry especially in the United States.

"The very first act of July 4, 1789, imposes upon indigo a duty of 16 cents per pound, which was gradually raised to 50 cents in 1812; after several changes it was put on the free list in 1842, then changed in the same year to 5 cents per pound, with several changes subsequently. Paints in oil and also soap shared substantially the same fate; crude saltpeter, on the other hand, was kept almost without exception on the free list and the same is true of brimstone. Sulphuric acid is first mentioned in the law of 1824, carrying the duty of 3 cents per pound; reduced in 1824 to 1 cent, put on an ad valorem basis in 1846; on the free list in 1861, and, after intervals, again in 1872 and 1894. Muriatic acid appears for the first time in the act of 1832, boracic acid in 1841, most of the other common acids in 1846, alum in 1876, aluminum sulphate in 1862, aluminum itself 10 years later, in 1872. Barilla (natural soda) appears first in 1816, carbonate of soda in 1832, and soda ash in 1841. One year later (in 1842) bleaching powder is specifically mentioned, while anilin colors are made dutiable at 25 per cent ad valorem in the law of 1862, five years after their introduction into industry. These few instances may suffice.

"The United States census of 1880 had established the fact

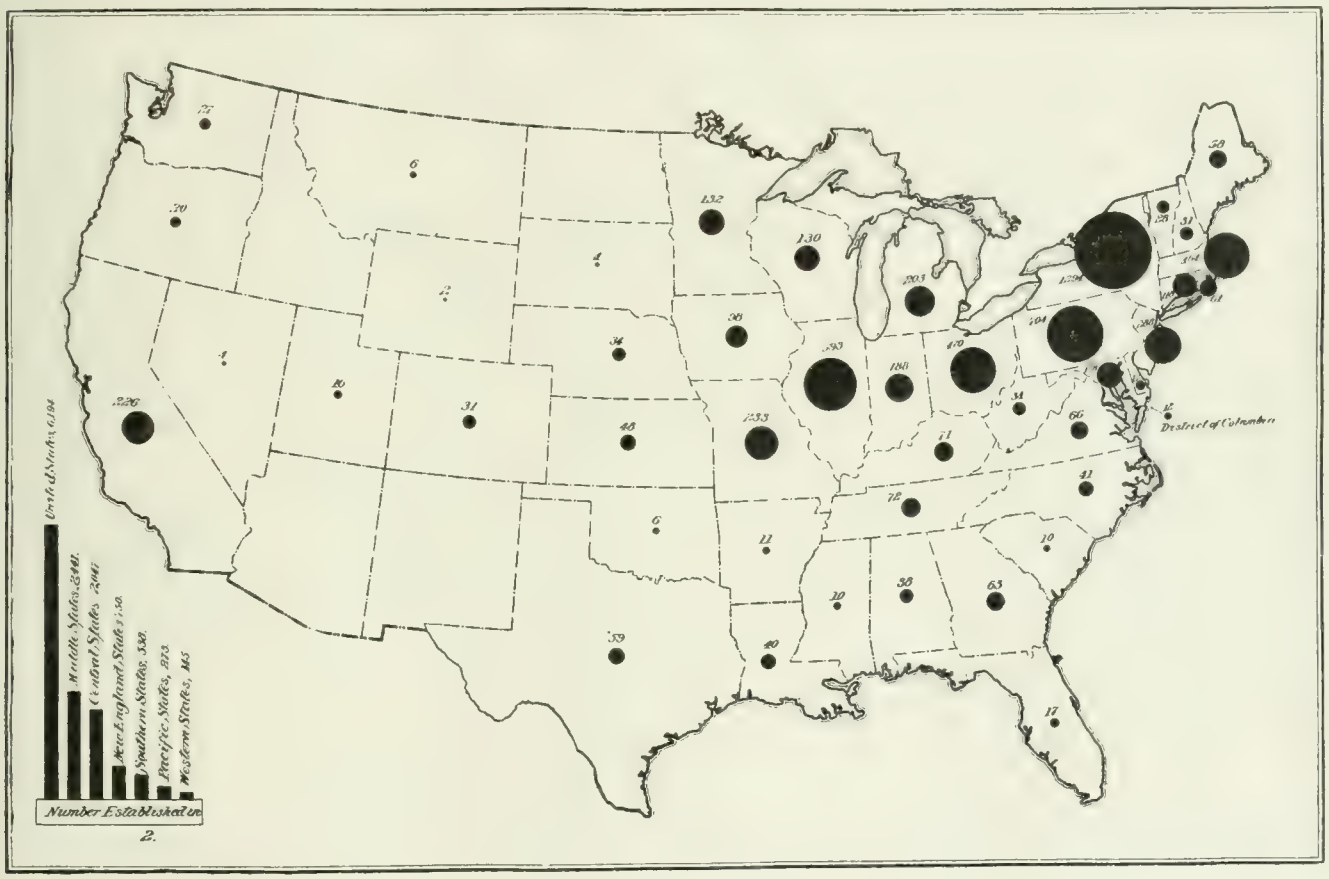


FIG. I.—GEOGRAPHICAL DISTRIBUTION OF CHEMICAL ESTABLISHMENTS AFFECTED DIRECTLY BY SCHEDULE A.

that chemical manufacturers occupied a prominent position among the industries of the country, and after the Tariff Commission of 1883 had recommended the subdivision of the proposed tariff law into generic schedules, each to comprise as much as possible a specific industrial group, chemicals, oils, etc., owing to their importance and their basic relation to other industries generally were assigned a group to themselves at the head of all others. Schedule A has since then remained the schedule devoted to chemicals, oils, paints, etc., and the general scheme of classification devised originally has in the main been followed in all subsequent revisions. Specific rates were changed or were altered to an ad valorem basis or inversely; single items were eliminated or added, put on the free list or made dutiable again in accordance with the policies of the tariff framers. . . .

"On account of the great and continuously increasing number of chemical products now on the market, their diversified

character and other distinctive features, a reclassification of chemicals on lines more indicative of their industrial and fiscal importance is made periodically by other countries, and it seems that in the United States much uncertainty and vexatious litigation could be eliminated if for the same reasons and to meet the same purposes a general reclassification were instituted at proper intervals."

The first part of the book (147 pages) is a Glossary on Schedule A, discussing the chemicals enumerated in the 83 paragraphs of this schedule, and giving in each case a concise elementary statement of the method of manufacture, with statistical data on home production and imports.

Schedule A comprises the following materials: acids, alcoholic compounds, alkalies, chemical compounds and salts, alumina, ammonia compounds, argols, blacking, bleaching powder, blue vitriol, charcoal, bone and blood char, borax, camphor, chalk, chloroform, coal-tar products, cobalt oxide, collodion and pyroxylin compounds, coloring for brandy, etc., coppers, drugs, barks, etc., ethers, extracts, blues and gelatines, glycerin, indigo, ink and ink powders, iodine, iodoform, licorice extract, chicle, magnesia, oils, opium, coca leaves, barytes, ferrocyanide blues, blanc-fixe, blacks, chrome colors, mineral pigments, orange mineral and red lead, ultramarine blue, paints, pigments and varnishes, zinc chloride and sulphate, Paris green and London purple, lead compounds, phosphorus, bichromates, caustic potash, potassium iodide, saltpeter, prussiates of potash, medical preparations, corrosive sublimate and calomel, druggists' preparations, plasters, perfumery, santonin, soaps, soda compounds, moss and sea grass, sponges, strychnine, sulphur, sumac, vanillia.

Schedule A comprises, therefore, quite a heterogeneous mass of compounds, and on the other hand covers only part of the chemical industry and none of the metals.

The geophysical distribution of the chemical establishments affected directly by Schedule A is given in an interesting manner in Fig. 1, giving both the number of establishments by states (1) and by grand divisions (2). New York with 1292 establishments is far in the lead, followed by Pennsylvania, Illinois, Ohio, Massachusetts, New Jersey, etc., the list being closed by the purely agricultural states like Wyoming, South Dakota, Nevada, Oklahoma, Montana, with less than 10 establishments each, while Arizona, Idaho and North Dakota do not possess any establishments engaged in the manufacture of chemicals affected by the present tariff law.

The second section of the book (100 pages) gives historical sketches of the evolution and present status of the chemical industries in the United States, Germany, England, France and Canada.

"The beginning of chemical manufacturers in the United States, even those included only within the narrow definition commonly assumed, dates back to a very early period of our history. The first sulphuric acid plant using lead chambers was erected in Philadelphia in 1793 by John Harrison, who only a few years later introduced the method of refining the acid from a platinum still and claimed for himself the credit of having been the first to introduce this very important innovation. The manufacture of white lead by Wetherill had even preceded this undertaking, and this, too, was located in the Quaker City, which was early an important center of industrial and scientific activity. Other chemical establishments followed, particularly those manufacturing drugs and medical compositions, pigments and extracts for tanners and dyers.

"From Philadelphia the industry spread to Baltimore and gradually to New York and the New England states, but it was confined exclusively to the making of certain chemical specialties with no industrial connection or unity between them. This is not surprising in view of the purely agricultural status of the United States in those days.

"But even after manufactures began to be established here conditions changed but imperceptibly, the number of new chemical establishments increasing only very slowly as they were able only with difficulty to withstand the pressure of the English competition, which at that time was world supreme and had every advantage in cheap supply of materials and superior knowledge and experience in the use of manufacturing processes. This apparently was the reason why the manufacture of soda ash by the Le Blanc process never gained a foothold on this side of the Atlantic and why this most powerful factor for the creation and expansion of a chemical industry in the United States was missing.

"In the second half of the nineteenth century progress was quickened. Petroleum refining, the increased demand for fertilizers, the development of the textile, tanning, paint, soap and other industries required a prompt and large supply of, and insured a satisfactory market for, specific chemical products, which American enterprise attempted by degrees to satisfy. The census of 1860, like all other census up to 1880, paid no particular attention to chemical manufactures, but by counting only such items as clearly belong within the group of manufacture of chemicals proper we find enumerated in its statistics 99 establishments which may be so classed, with an output valued at $5,251,225 and employing 1636 wage-earners who received in wages the sum of $561,672.

"These figures do not include potashes or lyes, medical compositions and pigments." A better appreciation of the status of the chemical industries of those days can be got from special tables prepared by the author from the original data as furnished by the census of 1860. These show that in 1860 there existed 3998 establishments for the manufacture of chemicals and allied products, with a total value of $91,696,156 of the products. "The total number of manufacturing establishments counted in 1860 was 140,433, and the total value of their product amounted to $1,885,861,676, so that the chemical industries were represented with 2.99 per cent in number of establishments and 4.89 per cent in value of product respectively."

"The two decades following from 1860 to 1880 were decisive periods in the history of the United States from both a national and economic point of view. The rearrangement which took place in the entire structure, economic and political, stimulated wonderfully the growth of manufactures, which during these 20 years almost doubled in the number of its establishments and trebled in the value of its products, the record for 1880 being 253,852 establishments and products valued at $5,369,579,191, mining industries not being counted. During the time the population of the United States increased from 31,443,321 to 50,155,783, or about 60 per cent.

"The chemical industries for various reasons did not share proportionately in this development of manufactures generally. Yet they had grown considerably in importance, their economic character showing a marked change, as evidenced in the value of output per establishment, which increased from approximately $23,000 in 1860 to $87,000 in 1880. The importance which the chemical industries had then already attained in the economic life of the Union is also manifested by the fact that the census authorities for 1880, for the first time in the history of census taking, saw the necessity of treating the chemical manufacturers as a single unit in a special report."

The number of establishments for the manufacture of chemicals in 1880 was 1349, with $85,400,000 invested capital and $117,000,000 total value of products.

The later development of the chemical industries of this country is shown clearly in Table I, giving quantities and values of products made by establishments engaged in the manufacture of chemical products from the census reports for 1899, 1904 and 1909.

An examination of this table illustrates sufficiently the status of the chemical industry in the United States according to the latest available data.

From a discussion of the import and export trade it is concluded "that the manufacture of so-called staple products, especially inorganic, is carried on on a scale fully commensurate with the demand. The same may be said of certain special

TABLE I.—CHEMICALS PROPER, DETAILED SUMMARY—PRODUCTS.

As per census of 1909, 1904 and 1899, from proof sheets of the census of 1909.

[1] In addition, products to the value of $8,329,440 were produced by establishments engaged primarily in the manufacture of products other than those covered by the industry designation, including: Acetic acid, 4,959,985 pounds, value $200,740; hydrofluoric acid, 2,051,951 pounds, value $79,722; muriatic acid 74,805,743 pounds, value $587,253; oleic acid, 2,959,346 pounds, value $165,091; stearic acid, 5,094,774 pounds, value $399,386; other acids valued at $49,530 (not including acids reported by manufacturers of explosives and fertilizers); sal soda, 10,822 tons, value $184,297; other sodas, 75,902 tons, value $1,835,278 (including sodas reported by manufacturers of paints and varnishes and fertilizers); potashes, 14,293,552 pounds, value $525,054; alums, 49,450,260 pounds, value $443,513; coal-tar distillery products valued at $1,610,792; hydrogen peroxide, 521,851 pounds, value $20,124; bisulphite bleaching materials, 3,062,000 pounds, value $23,650; other bleaching materials valued at $20,703; pyroxylin plastic, 292,582 pounds, value $282,560; anhydrous ammonia, 167,770 pounds, value, $40,923; carbon dioxide, 454,354 pounds, value $19,262; laughing gas, 24,500 pounds, value $4,900; oxygen, 23,826,325 gallons, value $79,319; other compressed or liquefied gases, valued at $9,072; chloroform, 8,250 pounds, value, $4,779; acetone, 2,007,560 pounds, value $210,287; glycerin, 1,022,920 pounds value $123,472 (not including 52,518,919 pounds, value $6,864,603, reported by manufacturers of soap); blue vitriol, 20,362,647 pounds, value $720,636; copperas, 3,031,566 pounds, value $53,372; phosphates of soda, 310,588 pounds, value $27,034; and zinc salts, 4,312,988 pounds, value $103,503.

[2] In addition, products to the value of $3,063,397 were produced by establishments engaged primarily in the manufacture of products other than those covered by the industry designation, including: Muriatic acid, 47,018,080 pounds,value $431,938; stearic acid, 1,750,000 pounds, value $140,000; hydrofluoric acid, 1,217,518 pounds, value $71,668; other acids, valued at $146,716; sal soda, 1,763 tons, value $29,561; caustic acid, 14 tons, value $668; other sodas 14,200 tons, value $363,765; alums, 33,074,349 pounds, value $532,185; coal-tar distillery products, value $238,645; bisulphite bleaching materials, 536 tons value $11,937; glycerin, 520,000 pounds, value $52,000; ether, 193,628 pounds, value $92,466; Epsom salts, 1,350,000 pounds, value $13,500; blue vitriol, 107,160 pounds, value $5,994; copperas, 81,816 pounds, value $586; and tin salts, 1,103,222 pounds, value $188,301.

[3] Not reported separately.

[4] Not reported.

manufactures, as for instance, fertilizers, soaps, paints, standard medicinal preparations, and some few others, the development of which has reached a state permitting of a considerable export trade. On the other hand quite a number of chemical manufacturers offer very much room for improvement in quantity, variety and in some instances also in quality of products made. Among these, and in the first place, must be mentioned the production of coal-tar dyes and coal-tar products generally, the manufacture of so-called 'fine chemicals,' high-priced extracts, and essential oils, and a great number of other products, consumed in relatively large quantities for a variety of purposes. Nevertheless, taken as a whole, the manufacture of chemicals proper during the intervening 10-year period has shown marked progress."

Details are given of the import and export trade with diagrams showing the fluctuations from year to year.

Quite extensive chapters are then devoted to the chemical industries of Germany, England, France and Canada

The Electrolytic Recovery of Tin from Tin Sheet Scraps in Italy.

Our contemporary, *Rassegna Mineraria Metallurgica e Chemica*, gives an interesting review of the Italian detinning industry with reference to official statistical reports of the Industrial and Commercial Public Survey of Italy.* According to this report there are three large Italian plants operating the electrolytic process. After several commercially unsuccessful attempts and the failure of one large establishment in the Valle d'Aosta, the following three plants were built in recent years and are now operating with complete success. The Dossmann Company in Pegli, the Eugenio Guecc in Arenzano, and the Societa Electrochimica Vesuviana in S. Giovanni a Tettuccio.

The first-named factory has been operating for five years, the first few years being devoted to such experimental work as every new industry requires. These investigations are partly still being continued, especially for the object of decreasing the cost of the process and for utilizing the by-products, like tin hydrate, which the company tries to work up into tetrachloride. We may give here the description of the process in an abbreviated form.

The electrolyte is a sodium hydrate solution of well determined concentration and temperature, the anodes being tin sheet scrap and the cathodes being iron plates. The tin is dissolved in the form of sodium stannate and deposited at the cathode as metal, while the soda is regenerated. The electrolytically produced oxygen dissolves more tin from the anode, while the hydrogen liberated at the cathode causes the tin to be precipitated in spongy form. The best results are obtained with only 2 or 3 volts per cell and a very low current density, which is never over 0.75 amp per square decimeter (1.16 milliampere per square inch). Experience shows that the most favorable concentration of the bath is from 10 to 12 per cent total alkalinity, the free alkali not exceeding 7 per cent. The carbonate must not exceed 3 per cent and the stannate not 5 per cent. The electrolyte is held at 60 deg. to 70 deg. C. and kept in continuous circulation. This is absolutely necessary in order to bring fresh tin into the immediate vicinity of the cathodes and to keep the electrolyte homogeneous.

The plant in Pegli contains nine tanks arranged in three parallel series of three tanks each. Each tank contains six anodes and six cathodes. The anodes consist of rectangular cages or baskets, made up of perforated iron sheets and contain from 100 to 130 lb. of tin sheet scrap. They measure about 39 in. x 35 in. x 18 in. The cathodes are iron plates 39 in. x 35 in. The bath is made up of a solution of 7 per cent to 10 per cent caustic soda, which is kept in circulation by a pump and reheated during this circulation in special heating tanks.

In order to be completely detinned the tin sheet scrap has to stay three hours in the bath, which means in view of the extra time for charging and discharging that each anode basket can be used for six operations in 24 hours. The electrolyte keeps at sufficiently uniform composition for two days and has then to be regenerated by addition of a certain amount of fresh solution. As an approximate rule, it can be assumed that about one-tenth of the solution has to be replaced every week.

After complete detinning, the contents of the anode baskets are combined in packets of 150 lb., and for thorough removal of the last traces of tin they are passed through a bath of the same composition as the electrolyte at 100 deg. C. and are finally washed twice in cold water. The better the tin is removed the better is the iron scrap for steel making.

The spongy tin is removed every 12 hours by carefully lifting the cathode and dipping it in water, the water tanks being held on a truck. Here the tin is held under water all the time. This precaution is necessary to prevent oxidizing of the tin by air. After the spongy material has been completely freed of soda by careful washings it is compressed in a small hydraulic press into 6-lb. cylinders, which afterward are melted in a furnace with sealed tubes. The sponge contains about 50 per cent metallic tin and 50 per cent ashes. These latter are mixed with powdered carbon and reduced in a little open-hearth furnace with another output of 70 per cent metal.

It is necessary to regenerate the tin contained in the discarded part of the solution. This is done by saturating the bath with carbonic acid under pressure, by which process the tin hydrate is precipitated. The sodium carbonate solution is then boiled in order to remove the excess of carbonic acid and finally treated with lime in order to regenerate the caustic soda. The slimes produced by introducing carbonic acid contain 15 per cent of tin. They, in turn, give an output of 40 per cent of metal in the reducing furnace.

The electric power is furnished by two direct-current dynamos, one producing 700 amp, the other 1100 amp, both at 27 to 30 volt. They are driven by a 35 and 50-hp power gas engine, respectively. The current is used mainly for electrolysis and for driving a 25-hp motor for the centrifugal pumps, the press, etc.

Every week this plant treats 50 tons of tin sheet scrap, or 2500 tons per year, with an average force of 20 to 26 laborers and one superintendent. It is equipped, however, for the treatment of double the quantity. The technical results are quite satisfactory. About 75 per cent of the tin is recovered in the metallic state. To this has to be added 6 per cent from the metal contained in the slimes of 15 per cent contents, and in the ashes of 30 per cent contents; considering, however, that for the tin regenerated from the slimes and ashes only half the price is paid, it appears that about 80 per cent of the tin can be sold. It is to be considered, however, that the tin contains up to 2 per cent of lead and a little iron and is, therefore, sold at a price 5 per cent below the price of tin produced from minerals.

The plant of S. Giovanni a Tettuccio, established in 1909, was built for treating 2000 tons per year. The same process as described above is applied here because it is found to be more successful than the use of an acid electrolyte and because the detinning with dry chlorine under pressure is considered to have not yet proven a commercial success. (The Italian official who compiled this report seems to have been unaware of the fact that in other countries the dry chlorine detinning process is rapidly advancing and has proven superior to the electrolytic process.)

The plant contains three batteries of electrolytic baths; each battery comprises three tanks, connected one to the other, with a capacity of 3 cu. m each, corresponding to approximately 85 cu. ft. The electrolyte is circulated by a pump which, from the level of each battery, lifts the liquid up into a huge vessel where it is reheated by steam coils. From this vessel the liquid is run back through the batteries. Each process lasts three hours and the operation is continuous day and night.

The electric energy is derived from a 27-volt, 1200-amp dynamo; the current density is little more than half that used in the first-named factory.

The tin obtained in spongy deposits is compressed in cylinders of 3 to 4 cu. decimeters (190 to 250 cu. in.), is then melted in tube furnaces and gives 70 per cent metal and 30 per cent ashes. From these ashes 70 per cent to 75 per cent metal is obtained by reduction in a small open-hearth. The rest remains in the slags, which are sold for further treatment in England. The residues are washed after complete detinning, compressed under 300 atmospheres into square packets of small volume and sold to steel makers. They still contain, however, 1/10 per cent of tin and a certain quantity of lead from the solder of the tin sheet scrap, this quantity of lead varying with the nature of the raw material.

The electrolyte is regenerated twice a week in the same way as mentioned above.

The operating details in the third factory are said to be the same as in the two others. R. A

Miscellaneous Cyanide Experiments.

By Louis Cohen.

In accumulating data pertaining to the testing of ores for cyanide treatment, I have noted some experiments, the results and comparison of which have afforded me a great deal of interest. They may prove to be of similar interest to others engaged in cyanide operations. A few of these experiments I will briefly describe, as they present some unusual as well as unexpected results. They demonstrate the effect of slight differences in the mechanical application of the methods of operation, and also the effect of the addition of other chemicals in connection with potassium cyanide. The increase in extraction of precious metals, the saving in cyanide, the gain in time of treatment which may be an economy in mill construction, and a reduced cost of treatment are some of the factors which enter into these results.

These experiments were made with the idea in mind of their practical application; that is, the working costs must be such as to make the use of the process profitable, and the mode of operation simple. The experiments also show the great variation in the results on the same ore under slightly different conditions, as well as the marked similarity in the results obtained from ores with entirely different characteristics.

It may be noted in some of the experiments that the extractions are so low and the cyanide solution of such strength as to seem unpractical. Further, the consumption of cyanide may seem exceedingly high. In all these cases it must be remembered that the experiments have been selected from a series, in order to offer comparisons along certain lines, and not to be considered apart from the series, except for purposes of comparison. For example, in one case it may be thought that the use of a preliminary wash would have saved an excessive consumption of cyanide, and such is absolutely true.

The experiments made to determine the most economical cyanide strength are not given. The object of this comparison is only to bring out the difference in the amount of cyanide consumed under varying conditions, and not to show whether it was practical to treat a particular ore with a certain strength of solution with its resulting high cyanide consumption.

Effect of Aeration of Slime.

The object of aeration in the cyanidation of ores is, of course, to supply oxygen which is essential for the formation of a soluble salt of gold and potassium cyanide.

When the gold has had sufficient oxygen present to form a soluble salt and still does not dissolve, it is considered not amenable to cyanidation. In other words, the mechanical condition of the gold may be such that it will not readily dissolve in cyanidation solution; or, a chemical combination may exist that is not acted upon by the cyanide solution. Then again, there may be a combination of these two; for example, a thin film on the surface of the gold may prevent the cyanide solution from attacking it.

The gold that remains in the ore and is still in the insoluble form after the completion of cyanidation is lost. The soluble gold is recovered to a considerable degree by washing and displacing the gold-bearing solution with barren solution or water. The insoluble form in the tailing may be amenable to some other form of recovery, as amalgamation or concentration; or it may be stored in a tailing pile for future treatment by cyanidation.

In the following two experiments, two kinds of gold are distinguished. The gold soluble in potassium cyanide which is held in the moisture of the wet slime, is termed dissolved gold; and the gold in the slime which is not acted on by the cyanide solution is termed insoluble gold.

It is taken for granted that aeration has been quite complete by agitation with air in a Pachuca tank, the ratio of solution to dry slime being 2:1 or greater. The aeration results on thick pulps will be shown to be better than those of the thinner pulps usually treated in Pachuca tanks. The experiments were conducted on quite different ores, and show remarkable results.

EXPERIMENT NO. 1. LEACHING TEST.

The ore was one generally known as an oxidized ore containing a small amount of heavy mineral in the form of pyrite. It assayed very low in gold. The sand and slime had been separated by classification, as is customary in plants which do not make an all-slime product.

The sand was subjected to leaching in tanks, and the slime was kept in suspension preparatory to treatment.: After agitating and aerating continuously for a number of hours, the slime pulp was filtered, leaving about 38 per cent moisture in the cake. Air was then drawn through for one minute, followed by a cyanide solution.

The slime previous to the aeration of one minute contained insoluble gold to the value of $1.22 per ton. After the aeration of one minute, followed by the cyanide solution, the slime contained insoluble gold to the value of $0.76 per ton. The difference of $0.46 in gold per ton was changed from insoluble gold to dissolved gold, due to the aeration and the application of the second cyanide solution.

EXPERIMENT NO. 2. LEACHING TEST.

The ore was a sulphide assaying high in gold. The insoluble gold in the slime assayed $0.44 per ton after cyanide extraction had been partly completed. The solution had been in contact with the slime for a number of hours, and aerated by agitation in a Pachuca tank. After filtration, air was drawn through the slime for one minute, followed by a cyanide solution. The amount of gold remaining in the insoluble form was nil. The difference in extraction of $0.44 gold per ton was due to the aeration and application of the second cyanide solution.

The results just given, confirm each other on two quite different ores. There exists a favorable condition for aeration in slime, containing a solution of cyanide in the form of 30 per cent moisture. Conditions for aeration are not so favorable in thin slime pulp with a ratio of two parts solution to one of dry slime. The factor of a second cyanide solution with a lower gold content enters into consideration, as well. The fact, however, is quite pronounced that after a number of hours' agitation and aeration, the effect of one minute more aeration materially affected the extraction.

In order to find out whether pure gold in potassium cyanide solution would be similarly affected, the following experiment was tried. It substantiates in a measure the importance of the time element in comparing the effect of air in solution with that of air on the surface of the liquid.

Effect of Oxygen at the Surface and Beneath the Surface of a Solution.

A solution of 8.2 lb. potassium cyanide per ton was made alkaline with sodium hydroxide equivalent to the extent of 1.5 lb. protective alkalinity. To some of this solution in a flask was added gold leaf in small particles, allowing some to float on the surface and the balance to sink. The flask was agitated gently to facilitate solution of the gold, but not sufficiently to cause the floating gold to sink. The gold on the surface of the solution was dissolved completely in 5 minutes.

The flask was then agitated more violently, but the time required to completely dissolve the gold which had sunk beneath the surface of the solution was 240 minutes. It took, therefore, 48 times as long to dissolve the submerged gold as it did that portion which was in contact with the air on the surface.

Effect of Aeration on a Sand Charge.

EXPERIMENT NO. 1. LEACHING TEST.

A heavy pyritic ore assaying $18 in gold was crushed to pass a 40-mesh screen. A portion was subject to continuous leaching with cyanide solution. Another charge was leached intermittently with cyanide solution, air being drawn through the ore between alternate leaching periods. A 10-lb. potassium

cyanide solution was used in this test after the same preliminary washes in each case. The cyanide solution, in the ratio of 1:1 of ore, was allowed to percolate through the charge six times in each case. The leaching time was 72 hours in the continuous experiment, and 18 hours in the intermittent; these being the actual periods of contact with the cyanide solution.

The results were as follows: The tailing from the continuous treatment assayed $11.20 in gold per ton, corresponding to an extraction of 37.8 per cent; the cyanide consumption was 13.5 lb. per ton of ore. The tailing from the intermittent treatment assayed $8.40 in gold per ton, corresponding to an extraction of 53.3 per cent; the cyanide consumption was 7 lb. per ton of ore.

This experiment was performed on coarse ore, and at the time of aeration there was present as small a quantity of solution as possible. It was the intention to find out whether gold in coarse ore would act in a similar manner to gold in slime.

The results probably would show a greater difference than they do if the results were expressed in terms of insoluble gold as in the slime experiments, but for certain reasons they are expressed as total gold in the tailings. In this comparison three points are prominent, all of which are in favor of the aerated charge, viz., approximately one-half greater extraction, one-half less cyanide consumption, and one-fourth the time of treatment.

EXPERIMENT NO. 2. LEACHING TEST.

An oxidized ore containing no sulphide minerals was crushed to pass an 8-mesh screen. It assayed $8.80 in gold per ton.

One portion was treated by continuous leaching, while another charge was leached intermittently, with alternate periods of leaching and aeration as described before. A 3-lb. cyanide solution was used, after the same preliminary washes in each case, at the ratio of 1:1 of ore. This solution percolated through the charge four times in each case. The leaching time in the continuous test was 43 hours, and 6 hours in the intermittent; these being the actual times of contact with the solution.

The results were as follows: The tailing from the continuous experiment assayed $7.60 in gold per ton, corresponding to an extraction of 13.6 per cent; the cyanide consumption was 3.2 lb. per ton of ore. The aerated tailing from the intermittent experiment assayed $7 in gold per ton, corresponding to an extraction of 20.5 per cent; the cyanide consumption was 1.6 lb. per ton of ore, and lime consumption amounted to 7.6 lb. per ton of ore.

The result of the experiment was that the aerated charge gave approximately one-half better extraction in one-seventh the time, with approximately one-half the consumption of potassium cyanide and lime as compared with continuous leaching. In these two experiments the ores were as different in character as it was possible to select, and yet the results show striking similarity in extraction and cyanide consumption. I do not mean to imply that these conditions would obtain with all ores, as aeration sometimes is not as essential for good extraction as it appeared to be in these cases.

Effect of Picric Acid on Cyanide Extraction.

EXPERIMENT NO. 1. AGITATION TEST.

A heavy sulphide ore containing a large percentage of pyrite was crushed to pass an 80-mesh screen. The ore assayed $8 in gold per ton. It was agitated for 19 hours in a solution containing 3 lb. potassium cyanide per ton, with lime as protective alkali. Another charge was treated with the same solution, but with the addition of 0.8 lb. picric acid per ton of ore.

The tailing from the regular cyanide treatment assayed $5.20 in gold per ton, corresponding to an extraction of 35 per cent of the gold value with a cyanide consumption of 6 lbs. per ton. The tailing from the picric acid treatment assayed $3 per ton, corresponding to an extraction of 62.5 per cent of the gold value, with a cyanide consumption of 5.6 lb. per ton

The result of this comparison shows an extraction approximately double, and a cyanide consumption approximately 10 per cent less in the case of the picric acid addition as compared with the regular cyanide treatment.

EXPERIMENT NO. 2. AGITATION TEST.

An ore assaying $16.20 in gold per ton was crushed to pass an 80-mesh screen. It was agitated in a solution containing 1.8 lb. potassium cyanide per ton, with lime as protective alkali. Another charge was agitated with the same solution, but with the addition of 0.5 lb. picric acid per ton of ore. The time of treatment and conditions were the same in each case.

The tailing from the regular cyanide treatment assayed $2.40 in gold per ton, corresponding to an extraction of 85.2 per cent; the cyanide consumption was 0.4 lb. per ton, and lime consumption 4.6 lb. per ton. The tailing from the picric acid treatment assayed $2 per ton, corresponding to an extraction of 88 per cent of the gold value, with a cyanide consumption of 0.4 lb. per ton and a lime consumption of 4.2 lb. per ton.

With this particular ore it is noted that the difference between the two extractions (about 3 per cent) is not as great as in the preceding test. Other tests with this particular ore showed that neither aeration nor oxidizers were essential to its treatment.

EXPERIMENT NO. 3. AGITATION TEST.

An ore assaying $8.80 in gold per ton was treated with a 10.5-lb. cyanide solution, with no protective alkali. Another charge was treated with a similar solution, with the addition of 0.5 lb. picric acid per ton of ore. The time of treatment and other conditions were the same. The tailing from the regular cyanide treatment assayed $2 in gold per ton, corresponding to an extraction of 77.3 per cent. The consumption of cyanide was 1.2 lb. per ton. The tailing from the picric acid treatment assayed $3.20 per ton, corresponding to an extraction of 63.6 per cent of the gold. The cyanide consumption was 1 lb. per ton.

The result of this experiment shows that the extraction in the straight cyanide treatment without a protective alkali was greater than that obtained when picric acid was used. The consumption of cyanide was practically the same in each case.

Effect of Lead Acetate on Cyanide Extraction.

EXPERIMENT NO. 1. LEACHING TEST.

A heavy sulphide ore assaying $18 in gold per ton was crushed to pass a 20-mesh screen. It was leached for seven days with a 2-lb. cyanide solution containing a protective alkali. Another charge was treated with a similar solution with the addition of 1 lb. lead acetate per ton of ore. The extraction by the simple cyanide treatment was 29.5 per cent of the gold, the cyanide consumption being 3.4 lb. per ton. The extraction by the treatment with lead acetate was 35.7 per cent of the gold, the cyanide consumption being 3.6 lb. per ton.

The result shows one-fourth greater extraction by the addition of lead acetate as compared with the simple cyanide solution.

Effect of Cyanide Solution on a Raw and Roasted Ore; Conditions of Roasting; Loss on a Copper Ore.

EXPERIMENT NO. 1.

The raw ore, which was a heavy sulphide, was crushed to pass a 10-mesh screen. It assayed $5.20 in gold per ton and 1.38 per cent copper. It was treated with a solution containing 5 lb. potassium cyanide per ton, 10 lb. of lime being added as protective alkali. The tailing assayed $5.20 in gold per ton, showing no extraction. The cyanide consumption was 7.6 lb. per ton, and the corresponding lime consumption amounted to 5.4 lb. per ton.

EXPERIMENT NO. 2.

The ore was charged into a hot furnace and roasted at a low heat, and continued at a low, red heat until most of the sulphur was burned off. The final heat was raised until the

roast was sweet. The roasted ore assayed 0.03 per cent sulphur and $6.80 in gold per ton. It was agitated with a 5-lb. cyanide solution, with the addition of 10 lb. of lime per ton. The tailing assayed $1.40 in gold per ton, corresponding to an extraction of 79.4 per cent, the cyanide consumption being 5.2 lb. per ton and the lime consumption 3.4 lb. per ton.

EXPERIMENT NO. 3.

The second charge of ore was put into a cold furnace, and the temperature gradually raised until the sulphur ignited. The furnace was kept at a low temperature until the sulphur ceased burning, and the final heat was then increased until the roast was sweet. The roasted ore assayed 0.02 per cent total sulphur and $7.20 in gold per ton. It was then agitated with a 5-lb. cyanide solution, with the addition of 20 lb. of lime per ton. The tailing assayed $0.60 in gold per ton, corresponding to an extraction of 91.7 per cent of the gold. The lime consumption was 11.4 lb. per ton.

For the purpose of better comparison the results of these three tests are tabulated below.

Exp. No.	Material	Sulphur per-cent	Extraction per cent	Consumption lb. Cyanide	Lime
1	Raw ore		0.0	7.6	5.4
2	Ore roasted at high temperature	0.03	79.4	5.2	3.4
3	Ore roasted at low temperature	0.02	91.7	3.2	11.4

The difference in extraction may be accounted for by the assumption that the gold was free and existed in the fissures between the crystals of mineral or in the fracture planes, and that it was not amenable to cyanidation owing to a possible surface coating. The condition after roasting was favorable to cyanidation, due to the removal of the protective coating. In experiment No. 3 this protective coating appears to have been almost completely removed. In experiment No. 2 the gold may have become partly re-coated. Whether these assumptions are correct, the fact remains that the results are quite remarkable and of considerable importance.

This ore contained 1.38 per cent copper, probably in the sulphide form. It is interesting to note that the consumption of cyanide in pounds per ton was 7.6, 5.2 and 3.2 respectively. This would seem to indicate that there existed in the raw ore a small amount of copper which readily consumed cyanide; that a part of this copper was changed in experiment No. 2 so that it did not attack the cyanide; and that in experiment No. 3 still more of the copper present as a cyanicide in the raw ore was changed to another form, which seems to be more acid than either of the first two, as indicated by the increasing lime consumption.

Effect of a Solution Without Protective Alkali Compared to a Solution Containing Protective Alkali.

An ore assaying $8.80 in gold per ton was treated with preliminary water and lime solution washes, and leached with a 9.7-lb. cyanide solution for forty-eight hours. The solution, in the ratio of 2:1 of ore, was passed through the charge four times. Another charge was leached with a 10-lb. cyanide solution which contained no protective alkali. The tailing resulting from leaching with cyanide solution containing protective alkali, assayed $5.20 in gold per ton, corresponding to an extraction of 40.9 per cent. Cyanide was consumed to the extent of 6 lb. per ton, and lime 19.3 lb. per ton. The tailing from the treatment without protective alkali assayed $2.20 in gold per ton, corresponding to an extraction of 75 per cent of the gold. The consumption of cyanide was only 3.4 lb. per ton.

This was a remarkable test, for the extraction in the acid solution was almost double that in the alkaline solution. Further, the acid solution consumed approximately only one-half the cyanide consumed by the alkaline solution, and there was a saving of all the lime used in the first test. While this is extremely interesting, it probably would be dangerous practice and should be attempted only with proper facilities, as great danger might attend the formation of hydrocyanic acid gas in the acid solution.

Denver, Col.

Mechanism of the Formation of Troostite.

By Denison K. Bullens.

At the Fifth Congress of the International Association for Testing Materials, held at Copenhagen in 1909, a list of definitions of the micrographic constituents of steel was adopted. The final report advocated the use of the term "osmondite" to cover the intermediary state in the conversion of martensite towards the more stable pearlite. That is, the generally recognized constituents troostite and sorbite are to be considered as intermediaries between martensite and osmondite on one hand, and between osmondite and pearlite on the other. That these two transition constituents can be readily recognized under the microscope, however, is clear to every student of metallography, and much objection has been heard concerning the "official" elimination of them.

FIG. 1.—STRUCTURE OF ORIGINAL EUTECTOID STEEL X 50.

The great importance of troostite is emphasized by the recent advances made in the scientific hardening and tempering of steels. These processes are no longer carried on in a haphazard fashion by many companies, but in conjunction with a careful study of the steel in question. This scientific investigation has naturally led to much research as to the nature of troostite; that is, the mechanism of its formation and its transition into the more stable pearlite.

Troostite has probably called forth a greater variety of opinions and theories from investigators than any other of the micrographic constituents of steel. A brief résumé is necessary to a thorough understanding of the subject at hand, and for this purpose the following have been taken from numerous English, German, and French periodicals.

Breuil[1] based his theory upon the proposition that troostite should be characterized by finely divided graphite. This has been entirely disproved by experiments involving specific volumes.

FIG. 2.—FIRST APPEARANCE OF TROOSTITE X 50

Boynton[2] has since admitted the error of his assumption that troostite is beta (pure) iron.

Rogers[3] considered it to be a solution of gamma iron, *i. e.*, a mixture of either ferrite or cementite with a solid solution of the two in gamma iron. This theory has met with no favor.

Kourbatoff[4] considers troostite to be a solution of elementary carbon in alpha iron. This theory was also advanced by Sauveur,[5] who puts forward the following series of suggestions. Austenite, a solid solution of carbon in gamma iron, on reaching the upper critical zone, has its iron transformed into the allotropic beta iron, forming martensite. In cooling still fur-

[1]Breuil, Sci. Papers, vol. ii., p. 623.
[2]H. C. Boynton, Journ. Inst. Iron & Steel, 1904, I., p. 262.

[4]W. A. Kourbatoff, Rev. de Metallurgie, 1905, II., 169.
[5]A. Sauveur, Journ. Inst. Iron & Steel, 1906, IV., 109.

ther, beta iron falls out of the beta iron solution (in the case of the hypoeutectoid steels). In passing through the middle critical zone, all the iron (being in the beta form) is changed into allotropic alpha iron, the alpha solid solution being troostite. And through the lower critical solution the troostite (alpha iron solid solution with carbon) is broken into its components, forming pearlite. Sauveur, however, does not insist upon a solution of elementary carbon, but allows the interpretation with the carbide in solid solution. Kourbatoff differed from Sauveur only in that he considered the carbon to be in elementary form, while the latter said "that it never has been shown conclusively that it was the carbon rather than a carbide which was dissolved in the iron."

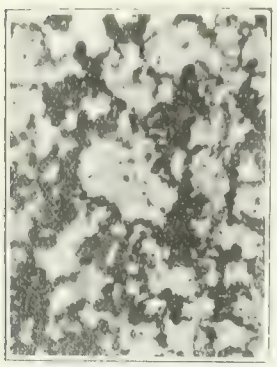

FIG. 3.—FURTHER INCREASE OF TROOSTITE X 50.

Benedicks[6] concludes from his researches that "troostite is a pearlite with ultra-microscopic small particles of cementite (containing also more or less hardening carbon). This is in keeping with the ease with which the troostite is affected by reagents, with its varying hardness—which lies between that of martensite and pearlite—and with the fact that troostite from a steel rich in carbon yields cementite when slightly heated, as Kourbatoff has shown. In all probability troostite is a transition in situ of martensite, which implies that the carbon it contains must be the same as in the martensite from which it originated. Troostite being more stable than martensite, the only possibility is that it is constituted of beta or alpha iron."

In a later paper[7] he advances the following additional arguments: a, the formation of troostite is not dependent upon the quenching temperature, but on the rate of cooling; b, the formation of troostite is accompanied by recalescence; c, the electrical resistance and specific volume are both the same as pearlite.

Fletcher[8], in discussing Benedick's first paper, states that troostite might be classed as carbide-saturated beta iron, containing also about 0.9 per cent carbon. He was of the opinion that troostite was not so hard as martensite: a, because beta iron was softer than gamma iron; b, the carbide or cementite was in a finer state of division than in martensite. He suggests that sorbite is composed of two pearlites, Fe_3C carbide in beta iron (troostite), and Fe_3C carbide in alpha iron (pearlite).

Campbell,[9] in an article on "The Constitution of Carbon Steels," explains the change from martensite to pearlite in the following manner: "The gradual change of the allotropic alpha iron is indicated (in the martensite) by a gradual loss of the needle-like martensitic structure and is replaced by the troostitic structure. Troostite is either a supersaturated solid solution of carbide of iron in alpha iron, part of which at least is under stress, or a mixture of solid solution of iron in allotropic iron with alpha iron and precipitated carbide of iron in particles too fine to be discernible under the microscope. With a rise in temperature the molecular freedom becomes greater and the carbide either precipitates or segregates into microscopic particles, and the internal stress of the alpha iron is relieved.

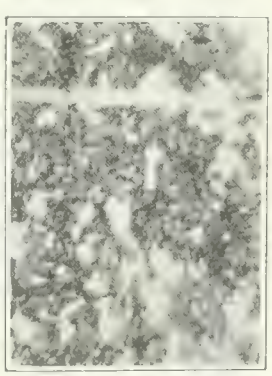

FIG. 4 FURTHER INCREASE OF TROOSTITE AND CHANGES INTO SORBITE AND OSMONDITE X 50.

"We now have sorbite."

Kroll, in an article[10] remarkable for the tremendous amount of reasoning involved, takes up the subject of the iron-carbon system from an entirely different standpoint—that of crystallography—from that usually adopted. His nomenclature is worthy of notice, and part of which is given here. He divides cementite into two classes. First, "cementite," free, hexagonally crystallized carbide Fe_3C, insoluble in iron. Second, "regular cementite," to which he gives the new name of "solvite." This latter carbide is the one present in solid and liquid solutions; dissolves gamma iron and is soluble in it; in a pure state, attached to and imbedded in austenitic grains, and at the same time often recrystallized in elongated regular cubes; quenched, it appears at most as pseudomorphs, consisting of hexagonal cementite. Troostite he defines as deposited solvite, more or less saturated with gamma iron. Regarding this latter he states that grounds were discovered for the assumption that the regular solution carbide (solvite) strives after saturation with gamma iron, thus forming the constituent troostite (the x constituent).

MARTENSITE AND [illegible] X 675

The general tendency of thought at the present time seems to be towards Benedick's proposition of an ultra-microscopic pearlite, regarding troostite as an aggregate. If this is true, there must be some point at which the ultra-microscopic particles become microscopic. There are, however, a large number of investigators who maintain that troostite is a solution of carbon (or carbide) in allotropic iron.

In either case, a rigorous microscopic investigation into the subject should throw additional light upon it. This will involve the use of as nearly pure steels as possible, and a heat treatment (the Metcalf test) which will give a continuous structure between and through the critical range. In other words, the study of the transition of martensite into troostite into sorbite.

[illegible] PRE-TROOSTITE X 675.

The preliminary requirement is pure iron-carbon alloys, in which the influence of such elements as silicon, manganese, phosphorus, sulphur, etc., is reduced to a minimum. For this purpose, special steels were obtained from the Halcomb Steel Company, of Syracuse, N. Y. The two grades of eutetoid and hyper-eutectoid steels were investigated by submitting 6-in. lengths of ⅝-in. rounds to the Metcalf test. That is, by heating one end to about 1050 deg. C., and quenching the entire piece in water. The pieces were then fractured lengthwise, polished, etched, and photographed. A solution of nitric acid in absolute alcohol was used in some instances, especially where it was desired to bring out the difference between martensite and austenite, as in Fig. 5. In the main, however, it was found that Kourbatoff's reagent gave the best results for the distinguishing of the troostite.

[6]C. Benedicks, Journ. Iron & Steel Inst., 1905, II., 352.
[7]*Ibid*, 1908, IV., 220.
[8]J. E. Fletcher, Journ. Iron & Steel, 1905, II., 366.
[9]H. Le Campbell, *Ibid* 1908, II., 321.
[10]A. Kroll, Journ. Iron & Steel, 1910, I., 382.

The composition of the steels used is given in the following table:

ANALYSES.	Eutectoid.	Hyper-Eutectoid.
Carbon	0.92	1.48
Manganese	0.14	0.10
Sulphur	0.011	0.006
Phosphorus	0.009	0.009
Silicon	0.14	0.14

It will be seen from the above that the minor components are so low that they will probably have no effect upon the micrographic constituents.

A continuous photomicrograph of several feet in length was obtained from each piece, representing the transition from austenite to the original steel. In all cases these showed, under low-power lenses, the familiar structure known to all metallographists.

FIG. 7—SAME AS FIG. 6, BRINGING OUT TROOSTITE AREAS X 675.

Fig. 1* illustrates the structure of the original eutectoid steel, showing both sorbitic and pearlitic constituents.

The troostite—in hardened steel—first appears at the boundaries of the martensite crystals as a thin black line, as shown in Fig. 2, increasing to greater width and with the formation of globules, as in Fig. 3. It soon occupies the whole of the section, but also begins to change into sorbite or osmondite, as shown in Fig. 4. This photomicrograph also shows the difference in hardness between the martensite yet remaining unchanged and the troostite, the latter being readily scratched with a needle. The same hardness results were also obtained with sections having a much smaller amount of troostite. Both the eutectoid and hyper-eutectoid steels in the earlier parts of the austenite transformation, when taken at 100 magnifications appear to have the same structure. But when we study the structure at very high magnifications—1350 diameters†—much more important features are observed, and throw much light on the mechanics of the transformation.

FIG. 8—PRE-TROOSTITE IN MARTENSITE AREAS OF TROOSTITE, AND LARGER AMOUNTS OF FREE CEMENTITES X 675.

Fig. 5, so etched with nitric acid solution and photographed as to bring out the martensitic structure, gives a wonderful insight into the first appearance of the troostite. The development of austenite (white) into needles of martensite (gray) is as many other experimenters have noted. But furthermore, there may be seen darker splotches forming at the intersections of the austenite-martensite grains. These spots are surrounded by little dots which seem to merge and agglomerate into the spots, which are troostite. We have here the change or precipitation, of the martensite needles into the embryo "germs" of what we may term "pre-troostite." The section corresponds to one even less further advanced in the transformation than that shown at low magnification in Fig. 2 on page 205.

*Cuts 1 to 4 are reduced in size one half from the original photographs, which were 100 diameters magnification.

†The cuts 5 to 9 are reduced in size one-half from the original photographs, which were 1350 diameters magnification.

Figs. 6, 7, 8, and 9, etched with Kourbatoff's reagent, are photomicrographs of the hyper-eutectoid steel at 1350 diameters, taken at sections showing a larger growth of troostite, together with its resolution. The precipitation of the "pre-troostite" is again shown as dots upon the white background in Fig. 6, together with the larger globular masses of troostite. Fig. 7 is the same as Fig. 6, except that the print was so developed as to bring out the structure of the troostite areas. The troostite has the pebbly appearance noted by many investigators, the more fully resolved than usual, due to the exceptional magnification. We have here also the first appearance of free cementite, which appears to be thrown out as veins.

FIG. 9—REARRANGEMENT OF TROOSTITIC MASSES INTO "OSMONDITE" WITH FIRST APPEARANCE OF PEARLITE X 675.

Fig. 8 shows the pre-troostite in the martensite, areas of troostite, and larger amounts of free cementite. Here we have the free cementite with the familiar spine-like growth branching out from the main veins. It will be noticed that the free cementite appears only in the troostite.

Fig. 9, at a much further advanced stage in the transformation, shows the rearrangement of the troostitic masses into that which would be called "osmondite" by many, together with the first appearance of pearlite (lower left-hand corner).

We may now sum up the various transitions as follows:

(a) Austentite.

(b) Martensite, appearing as needles, characteristic.

(c) Precipitation (or change) of infinitesimal particles of pre-troostite (elementary troostite) from the martensite.

(d) Segregation of pre-troostite to the boundaries of the austenite-martensite grains, forming splotches (veins, under low magnification) and globular masses. Metallographically known as troostite.

(e) Differentiation, almost immediately following the segregation, of the troostite into osmondite, together with the precipitation of free cementite in the case of hyper-eutectoid steels. The osmondite, from the pebbly appearance, is probably made up of the individual constituents ferrite and cementite.

(f) Mechanical arrangement of osmondite into sorbite and pearlite.

From a study of these and other steels, as well as a close investigation of the photomicrographs of other experimenters, the author believes that the masses generally known as troostite may generally be termed osmondite; that the real troostite is that shown by the dots in the photomicrographs. The change after segregation is so rapid that the resolution of the segregated troostite takes place almost immediately, giving osmondite and cementite—in hyper-eutectoid steels.

The Important Factors in Blast-Roasting.

By H. B. PULSIFER.

(Concluded from page 159.)

6. *Greenawalt Down-Draft Pans.*

A Greenawalt pan was successfully operated at the Modern plant, near Denver, Colo., in 1910. An account of the operating is given by Austin, Mineral Industry, 1910, p. 186, but the following may well be added:

Construction began in December, 1909, but various delays prevented operation until February, 1910. One pan only was in service almost continuously from then until the plant closed down in June, 1910.

The material sintered was copper concentrates and flue dust. This mixture was just such a one as others have not been able

to sinter successfully on account of the fineness of the material. Many of the first trials were flat failures, and good results came only when it was found that the moisture content was the vital point. Charges which could be ignited only in spots and utterly incompetent of complete sintering gave splendid sinters when properly moistened and thoroughly mixed. Depending on the fineness of the charge up to 15 per cent water had to be added.

The regular charge for sintering consisted of about 3 parts of flue dust with 1 of concentrates. As the flue dust contained only some 7 per cent. of sulphur the concentrates supplied most of the fuel value. Larger proportions of concentrates could be used, even up to 2 parts of concentrates, with 1 part of flue dust. All intermediate proportions made good sinters, but for the requirements of the regular work the first was used. The sulphur content varied from 12 to 15 per cent., and seldom exceeded 16 per cent.

At the Modern plant it was desired to *sinter* the flue dust and concentrates, not primarily to desulphurize. Accordingly no special attention was given to the sulphur elimination. The charges were dumped red hot and smoking, and as soon as the material had agglomerated. This eliminated about 50 per cent of the sulphur, whereas longer treatment would eliminate 75 per cent.

With the comparatively low sulphur of the charge, its high silica content, and practical absence of lead, no ill effects resulted from forcing the draft. It was found that the time of operating could be materially reduced by raising the suction. From 1 hour with 12 inches of water suction the time fell to 45 minutes, with 16 inches, and finally to about 35 minutes with 20 inches suction. The Garden City fan, first used, proved unequal to the task; it had been designed to run at 3,000 r.p.m., and as run at 2,600 gave 16 inches suction, when speeded up to 2,800 it went to pieces. A rotary blower, next used, supplied the 20-in. suction, which would agglomerate a cake in about 35 minutes.

If lead to the extent of 2 or 3 per cent. happened to be present in the charge the sinter only improved in quality from the good fluxing properties of the lead.

To remove the fume and keep the blower in good condition a small stream of water was admitted into the blower. About 1,800 cu. ft. of air were required each minute.

Considerable fines, up to 15 per cent., were made when the cake from the pan was dumped onto the breaking grizzly below. This might certainly be improved upon for larger installations.

The process, as a whole, proved so successful and acceptable that a second pan had already been cast and a new and stronger wheel for the original fan was already on hand when the plant closed down. The second pan had a capacity of 2 tons per charge, as did the first.

For the blast furnace smelting the sinter proved of exceptional smelting qualities; its quick and easy fusion, its physical condition and fluxing properties rendered it available for irregularities in the furnace, where it came in demand to use instead of slag.

The second installation of a Greenawalt down draft pan was made at the Midvale plant of the United States Smelting, Refining Mining Company early in 1911. Sufficient operation proved that, although a better roast and sinter could be made with the pan, and that its operating cost would probably be acceptable, its capacity on the charge provided was much less than that of the stall units already long operated. Small scale experiments indicated that the capacity of a large pan would more than equal to tonnage of the stalls. In actual operation, the mixture provided was so very much different from the ones easily made for a little cake that the results were disappointing. High sulphur charges which slag and matte with up-draft blast, merely hold their heat and refuse to finish under the influence of the suction; the low sulphur charges have no heavy ignition to do the roasting in place of the internal fuel, and leave raw patches.

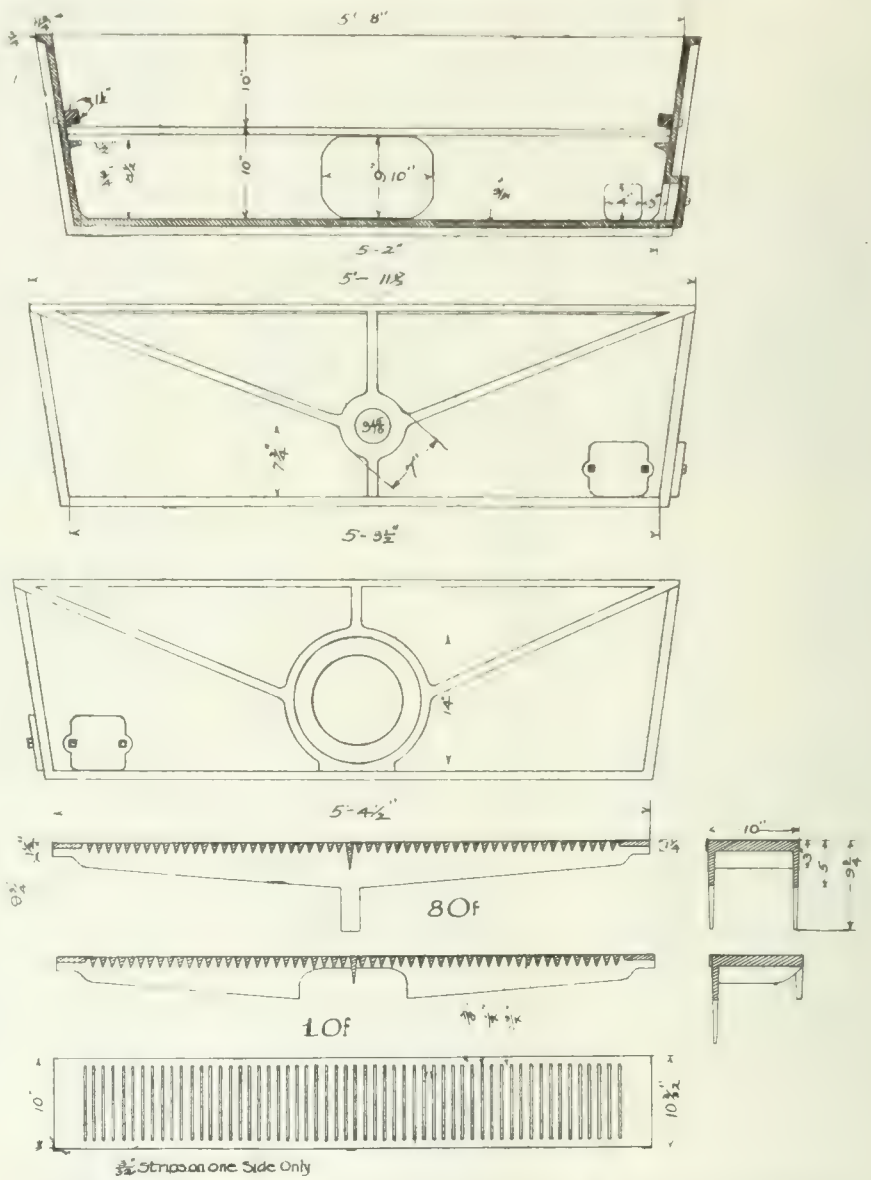

FIG. 3—SECTION AND END VIEWS, WITH DESIGN OF GRATES, OF GREENAWALT DOWN-DRAFT PAN.

After the working of over a hundred tons on the pan three of the regular stalls were slightly remodeled and connected with the fan which had served the pan; some 2,500 tons of product were then made, using suction and the regular charge. This attempt also proved disappointing in that the tonnage by no means equalled that of the regular stalls.

The down-draft system is characterized by the gentleness of

the action; there is no enormous generation of heat in an igniting bed of glowing coal and high sulphur concentrates; in fact, if glowing coal be spread on top to ignite the charge, the first burst of air through the originally porous charge is apt to so fuse the top layers that the pores are permanently closed and the rest of the desulphurisation indefinitely prolonged. The briefer the ignition, provided that the top layers are once fully lighted, so much the better will the subsequent roasting proceed.

With the gentle ignition follows a roasting and sintering equally unostentatious. Where the charge is of exactly the proper constitution there is very little motion of any of the particles; with slight contraction the cake finally becomes cold and dead. Any departure from this condition only delays instead of rushes operations. The mixture should be so uniform that each little layer will come to a glow and pass the fire on to the next, itself becoming cold.

In the fairly thin layer of all suction work the draft is from one broad free surface to another equally broad maintained at the grate. Every tendency is to close and not to open a channel for the draft. This is diametrically opposite to the tendency in all up-draft work. Accentuated by high sulphur, or too much fuel, in the mixture, the result with down-draft is some matting, but, more prominently, undue prolongation of the operation. Too much fuel in up-draft work does not necessarily so much prolong the operation as it fuses and mattes and creates blow-holes.

Those conditions which the Greenawalt pan requires are not to be considered difficult or costly of attaining. On a large scale mixing is well and cheaply done, with substances more difficult to handle than the granular ore mixture. The regulation of the moisture is not difficult to handle when the proper consistency is known; one or two per cent. from the ideal percentage is of small consequence.

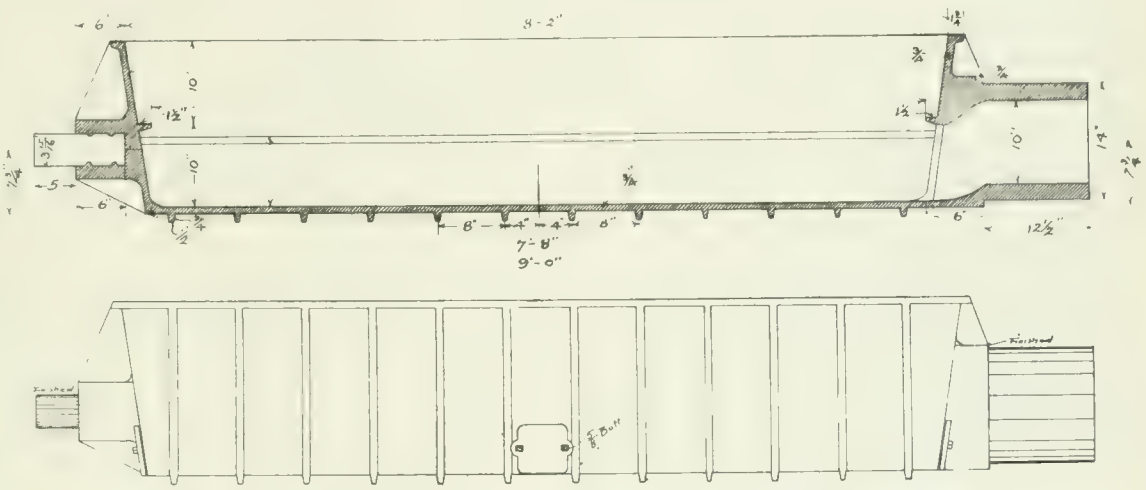

FIG. 4.—LONGITUDINAL SECTION AND SIDE VIEW OF GREENAWALT DOWN-DRAFT PAN.

Typical abnormal charges:

	Wt. Cu. Ft.	Lbs.	Moist.	Pb.	S.	Fe.	Insol.
1.	Too much concentrates	137.5	6.1	11.9	20.5	30.0	19.5
2.	Dry and fluedusty	137.0	4.8	16.4	19.0	26.5	16.0
3.	Too wet	135.0	9.0	16.0	17.2	30.1	19.7
4.	Too silicious	124.0	6.1	12.7	13.3	27.1	25.2
5.	Too dry and fluedusty	118.0	8.4	14.0	19.9	23.0	14.0

It must be borne in mind that, although the average composition of a large batch may be exactly right it will not answer that the mixture as fed into the pan may depart from this average to any considerable extent. The average of the above charges would make an excellent mixture and sinter well; the individual charges are in no case suitable. Mere inspection is sufficient to indicate the abnormality, but the analyses tell to what exact extent. It requires some engineering to have the conditions uniformly correct.

With the dumping pan low operating costs can certainly be attained. The units require but a few minutes for charging and igniting, and then no attention until the roasting is complete. A spring is pressed back, a little push or a slight pry with a bar and the unstable pan swings over, the cake drops out and the pan swings back, to be again caught by the head on the spring.

Moving parts or parts requiring attention are at a minimum. The pan used at Midvale had an effective bed depth of 10 inches. Two tons of the heavier mixture could be accommodated at one charge. A conservative estimate of the tonnage, based on actual operation with mixtures of mediocre suitability is that a cake of 1.8 tons roasting to 70 per cent. sulphur elimination from 15 per cent. lead and 19.0 per cent. sulphur should be dumped 7 times in 24 hours; that is a tonnage of 12.6 tons per 24 hours. On this same rough-and-ready charge either H. & H. pots or converter stalls should make an output of 16 tons per 24 hours.

With better mixtures the capacity of the pan should increase much, and it is believed that operating cost and cost of repairs and maintenance cannot be kept lower by any other type of equipment.

The cast iron pan at the Modern plant suffered no damage; the Midvale pan cracked in service, but was repaired and continued in use. Each time the pan dumped it received a severe blow, not wholly uniform, on one side, which came in contact with a wooden bumper in front of a steel beam of the floor. The analysis of the iron in the immediate vicinity of the crack indicates a good iron of the accepted quality for casting and machining, but of no particular strength and toughness.

	Per Cent.
Silicon	2.45
Manganese	0.25
Phosphorus	0.98
Sulphur	0.11
Graphite	2.74
Total carbon	3.18

The particular advantages of the Greenawalt method are:

Simplicity of operation and operating parts.
Low cost of operation and handling material.
Small amount of fines, from breaking cake mainly.
Slight volatilization of lead or other values.
Practically no flue dust, slight fume, slight SO_3.
Ideal physical structure for furnace smelting.
Low cost of ignition, breaking product, and maintenance.

Continued experience should result that newer plants have smaller operating cost due to the better design. When we have added to this the apparently superior principles of down-draft roast-sintering there apears little hope for the older methods. Estimates of the cost of pan-roasting will be given in the sequel.

V. Engineering in the Roasting Department.

With the advent of blast-roasting and the establishing of more or less standard mixtures which must be fairly closely adhered to for success the attaining of low costs settles down largely

to the operation of machinery and the handling of materials. With hand reverberatory roasting the great cost was to pay for manual labor to use as a source of power. The new method dispenses almost entirely with this factor and we pay for power as generated from coal or electricity, labor cost is the price of operating the equipment, and instead of buying brick and fireclay the cost of repairs is now the price of new wearing parts and replacing corroded steel.

The engineer is called on to meet conditions of novel variety. How shall we store continually varying raw material so that it may be drawn off for sintering with its composition fairly constant, so that the coarse and fines shall always be in the same ratio? How shall we keep moist material from freezing in severe weather? How best keep moist material from drying out during hot weather? How best convey the moist and sticky charge from mixer to roaster unit? How best dump a charge from hopper to unit without segregation? What is the best method of producing high suction? These and a multitude of other questions arise when the problem comes to handle and treat the variety of material to so many processes with a limit to the capital expenditure and operating cost.

The components of the charge are to be obtained of uniform character, accurately weighed, thoroughly mixed, suitably moistened, placed in the roaster unit, sinter-roasted, discharged and removed for storage. The rest of the paper will be devoted to a brief discussion of the sequence and carrying out of these manipulations.

1. *Preparing the Charge.*

There is apparently only one satisfactory condition in which material may be received either at the sampling mill or at the roaster bins—dry. To accept either concentrates or ores in any other condition means greater error in original weights, moisture, sampling and distributing, besides far more difficulty in unloading.

The chief concern is naturally to be able to get the material out again and to get it out always gradually in small parcels and always of the exact mean composition whatever particular method of storage be used. To attain this the material must certainly be first uniformly unloaded. From the metallurgist's point of view it is a pitiful sight to see a sample man standing on an island of coarse concentrates in a steel car, the mud and slimes surround him on all sides and he tries to get into a small pail something which shall represent how wet it all is. What good is a sulphur determination from shovel sampling such a mess, just as certainly now, as later, we may see the ill working and high sulphurs resulting in the final roast. Aside from direct unloading, possibly using steel troughs, and hand spreading below, there is no conspicuous method applicable to unloading.

The sampling of either dry concentrates, or silicious or other ores for diluting matter, may be carried out sufficiently well for the roasting department by shovel sample at the time the cars are unloaded. Concentrating plants would certainly find it to their advantage to send out their product fairly dry and well mixed. This should add no noteworthy burden of cost to the mill, and might eliminate considerable guesswork as to their own efficiency; the smelter could well afford to allow a small bonus for the good service, or even penalize the opposite.

As to the sampling of the silicious and iron ores which are necessarily mechanically sampled in a mill, and whose fines are to be screened out for diluent, it may be said that no extra cost is justifiable for this service. A well designed and efficient mill handling several hundred tons of ore a day and sampling at a cost of 10 to 15c. per ton should do the screening for a fraction of a cent, only, additional; to crush everything to half-inch, or thereabouts, a couple cents might be added.

If raw, massive sulphides are to be crushed and roasted they should be reduced to pass a screen with ¼-inch mesh. The diluent need not be reduced quite as fine, but it will do no harm; nothing larger than ½-inch has any place in blast-roasters. Besides losing its intrinsic diluting effect coarser material inevitably segregates from the fine; this is very important, for the material must needs be handled several times and the un-mixing itself, without any cumulative effect, will be found bad enough.

The weighing of the constituents of the mixture presents no particular difficulty, although certain errors are to be avoided. Multiplicity of scales and the placing of scales in unfavorable locations is not only a source of serious error but costly. Standard railroad platform scales, when properly cared for and regularly tested and adjusted, will answer every purpose for making large beds or mixtures of several hundred tons. Smaller platform scales serve for weighing into tram cars or ordinary mine cars; in this case it is best to provide only one or two scales, using these much and keeping them in good condition. Great care must be taken to keep the tare of the cars correct.

A smelter weighmaster will probably return the weight of a 50-ton car of ore to within 200 lbs. of its correct weight; that is, he will probably weigh to within 1 part in 500. The usual scaler in a smelter who receives about $2.25 a shift, when weighing out ton batches into a 3-ton tram car, will be doing splendid work if he gets his ton lots weighed to within 10 lbs. of what they actually are; this is to 1 part in 200. Besides the natural bother of weighing to mark the tare in the latter case is extremely difficult to keep adjusted. In attempting to accurately gauge small parcels of material it is more than likely that a system of measuring, indirectly referred to its weight, will be found more satisfactory. Mechanical feeding devices appear the proper thing for this work, especially for feeding from bins onto conveyor belts which will carry the material to the mixer.

Storing the supply of concentrates and crushed ores has already been touched upon; bedding the individual components in alternating layers and drawing off a vertical section which is again mixed and conveyed to the hoppers satisfies all demands and quite likely supplies as uniform a charge as may be obtained. However, in this case there is the expense of spreading and a further considerable capital outlay if arrangements are made to draw off the material into cars run beneath the beds. With uniformly fine material, such as concentrates, either flat or hopper bottomed bins might be used, but without spreading, segregation almost certainly results, and they are difficult to draw without again involving the same difficulty. A variety of methods of storing the materials might be suggested besides these more common ones; particular attention must be given for the abnormal conditions of wetness and severe freezing weather. Besides promptly doubling the cost of this part of the work, freezing not only may greatly decrease the tonnage but the charge cannot be mixed, it roasts poorly and the product is bad.

If the material is assembled in beds it may be drawn and sent directly to the mechanical mixer. If the material is drawn from separate bins it may be first assembled into cars and transferred to the mixer, or run onto conveyor belts or onto the same belt and delivered to the mixer. For existing plants this item of cost is usually rather high; in these plants the roasting department has often been built after the plant was laid out; in planning for new plants or rebuilding old departments foresight may easily save a few cents per ton by happy combination of method and arrangement of parts.

The mixing of the charge has already been referred to as of vital importance; hand mixing is not only costly and inefficient but does not do the work. Of the mechanical mixers available in the market the batch mixers probably give the best results for the reason that the material may be retained sufficiently long for thorough incorporation. If any continuous mixer should accomplish the same it would be available. Concrete mixers are handy and reliable, while for large tonnages other designs might serve better, the points of importance are that the mixing shall be complete, the batch must be visible so

that its consistency may be seen and more water added if necessary, it is best if the stuff is not only tumbled but incorporated with blades or baffles, the machine should not choke easily and as little power as possible required. If much lumpy slimes or fluedust or baghouse dust is to be worked in, the short tumbling and small cubic content of ordinary concrete mixers is hardly sufficient.

Pre-roasting is certainly an important consideration in the preparation of mixtures for the H. & H. process. That it can still survive and in conjunction with the roasting pots produce a product at such a low cost speaks well for its simplicity and low operating cost; indeed, a man to bring up the ore, another to care for the roast and one to fire is the full complement for a battery of several. It is an expensive method of preparing the primer for a pot but it also reduces the amount of diluent which would otherwise be required. This is possibly desirable with up-blast work where some ores are too rich and better briquetted but hardly offers any incentive with down-draft installations.

Depending on conditions, the cost of pre-roasting will be from 25c., as given by Huntington and Heberlein, to 63c., as given by Ingalls. Tonnage and kind of material are the great factors.

Considered in its ultimate economy, pre-roasting of pyritiferous ores is on about the same basis as crushing coarse iron ore and adding it for diluent in the roasting units; either method produces a sinter high in iron which will be balanced by new silicious material at the blast furnaces. To add the diluent in the shape of screenings of both silicious and irony material, thereby ridding the furnace burden of fines and putting all concentrates, fine material, flue dust and baghouse dust into porous sinter promises the lowest total smelting cost and best recoveries.

Allowing 5c. a ton as expense of spreading in beds and 3 men to assemble, mix and transfer to the units, with 2c. per ton added for power, the cost of preparing the charge is:

Bedding	$0.05
3 men @ $2.00	0.06
Power	0.02
	$0.13 per 1 ton

provided 100 tons are handled each shift. Supposing the original design and character of materials supplied are both good, it does not seem impossible that 2 men and the same power should do the work eminently well. This is, then, an estimated cost of 6c. a ton for preparing the charge.

2. *The Roasting Operation.*

The charge once prepared and assembled over the roaster unit those operations pertaining to the roasting act itself may be said to begin. As commonly carried out, these separate steps comprise this duty: charging the units, igniting, blowing or sintering, and emptying or discharging.

After the assembling and mixing and moistening of the charge it has quite a sticky consistency, the proper consistency for it to best sinter is exactly that at which it flows through an opening or in a trough with most difficulty; in other words, that at which it best retains any given shape. From this it follows that we must not expect to put it in a large hopper bin over the units and be able to draw it without considerable difficulty; besides the possible segregating we now have a mass which will not pack easily nor flow easily; in fact, it is just what we want and we must merely adapt conditions to handle it properly. Anything more than a small, simple and wide-mouthed hopper directly over the unit can have only two advantages; one is as storage to equalize irregular supply, the other, that storage disseminates the moisture very nicely and uniformly; both of these advantages, to my mind, do not compensate for the disadvantages involved. Any cars or hoppers handling prepared charges will thus be steep-sided and with wide months. If conveyor belts are used, ample provision is made to brush or to scrape the belt directly after it discharges.

If the charge is dropped upon the grate of the unit, this already made ready with protecting bed or burning igniting material, the fall is broken with appropriate strips of plank or steel; it is quite as readily slid down a wide and steep trough. Once in the unit, the sticks are removed and the material spread with hoe or shovel; suction work requires an additional smoothing with a rake; any coarse bits on top are also removed, as they hinder ignition.

The igniting has already been quite fully described for all types in the literature, and, with proper preparation of the charge, presents no particular difficulties. The ignition with oil or suction equipment is likely the cheapest of any method; this need not exceed a cost of 5c. per ton, which is a lower figure than we are aware of as otherwise attainable. For use in the fine nozzles the oil must be free from grit and scale and the fittings well made.

The sintering follows fast and well if the previous work has been well done; nothing will avail in the units to compensate for poor preparation. With any type of unit the blast or suction is turned on and results awaited.

The factors of moisture, fineness, uniformity, sulphur, lead, iron and silica in the mixture have been pretty thoroughly discussed and their limits defined. More than already stated, it is to be noted that some zinc is usual in all ores and concentrates; up to 3 or 5 per cent. its effect is certainly not more harmful than possibly giving higher sulphur in the product. Sulphide ores containing more than this amount should be milled for its separation. Flue dust well incorporated into the mixture does no particular harm even if it does contain large amounts of arsenic.

The blast regulation at the unit is more to compensate for faults elsewhere than as belonging to this detail of sintering, except with up-draft pots or stalls where the blast is cased or shut off while the blow-holes are punched. The sulphur, arsenic and lead fume from suction units will accumulate in a fan placed near the unit; the fan is thus to be made with the case split horizontal and hinged so that it can be quickly opened and cleaned. A large fan placed at considerable distance from the units and supplying several with suction will have slight inconvenience from the small amount of fume made. A few pounds of the sticky fume will put a small although powerful fan entirely out of commission; in a large flue this might collect for months before requiring removal.

When the operation of roasting and sintering is completed or has been carried as far as practical, the discharging takes place according to the particular equipment installed; any particular cost for this part of the work should be eliminated. Thus, at Midvale, the services of the ram man and the crane chaser are practically devoted entirely to this detail, involving a direct cost of 4.5c. per ton. With the Greenawalt pan, which is in unstable equilibrium when loaded, a slight push inverts it and the cake falls out, breaking on the angle irons below and sliding off into the steel boat or skip placed below, ready to be taken to the breaker.

The Dwight-Lloyd machines are supposed to work equally simple and with the same minimum cost.

Nothing more complicated or costly of operation will be tolerated in future design; even for these simplest cases one must bear in mind the properties of the material and use no material or construction which would be quickly damaged by the hard, rough and hot cakes in their entirety if, perchance, they should not be broken as expected.

Referring to the data already given, the labor cost of the roasting operation is given as 20.7c. at one plant, and for the other plant we may likewise find a sum of similar items which will amount to 6.3c. For a Greenawalt pan we may properly estimate that 2 men, whose pay shall equal $4.00 an 8-hour shift, will be able to dump and load a pan every 15 min., or handling a tonnage of 60 tons per 8 hours their labor will cost 6.7c. per ton. If we add to this the services of another man

to clean grates and the fines from beneath the grates we shall have a cost for labor of approximately 10c. per ton. This item of operating cost for the Dwight-Lloyd machines might be supposed to be somewhat less.

To furnish the blast or suction requires more power than the sum of all the other power requirements in the roasting department.

If, let us say, 100 continuous horse-power is required to supply air to treat 300 tons of material per 24 hours at a cost of $30.00 per horse-power year the cost is very nearly 3c. per ton.

Depending upon the cost of coal or of the electricity, this item is in so much a variable factor; the price of coal at most lead smelteries, due to the long haul, will hardly be at a low figure and the price of power will probably be much greater than in this last instance. In the case of two plants already considered the cost of power has been estimated at 9 and 10c. per ton of product, respectively. Without further explicit data the cost of a suction plant will be assumed at this same figure (9c.) per ton.

3. Crushing and Loading.

The employment of hand labor, alone, to break and load the product of the roasters is altogether too expensive to be considered where the amount of product is as large as is likely to be found in any permanent lead plant. A certain development in learning how to treat the roast mechanically is to be recorded, but, the usual cost of this operation is evidently far greater than will long be tolerated.

Allowing a crane man, a hoist man and 3 laborers as at work on this detail to care for 90 tons a shift the labor cost is about 11c. a ton. The question arises, should not a hoist man and one laborer be sufficient, and we inevitably answer that we believe the plant could easily be so designed that with not more than present power consumption this amount of labor can do the work. The tough, hard, massive and hot cakes commonly made with up-blast must first be broken before going to the crusher; even then an inordinate amount of labor is consumed in pounding, prying and turning about the big pieces before they settle into the jaws of the crusher. To use a Blake-type crusher of larger size than 24 in. x 36 in., which is a common size, is evidently not practical; it is, however, not so difficult to imagine a set of slow-turning and massive rolls above the crusher, whose teeth should engage and draw in the cake to be broken and passed down to the crusher for final sizing.

It ought not to be too difficult to plan and construct units so that a skip could catch the finished cake and carry it directly along and up and over the crushing equipment, dumping it and returning for the next load. Meanwhile, we suppose the cake to have fallen in, been crushed, and is now dropping down into the railroad cars which enter directly beneath. We thus come to estimate a cost of only 5c. per ton, which we presume will more than likely be bettered in the plants of the future. In particular with down-draft work, which produces a much more open sinter than up-draft, this estimate will be reasonable enough.

In regard to handling this type of material with elevators and conveyor belts, or conveying steel buckets, the burden of proving adaptability is still evidently on the apparatus. Skips are proving their usefulness in many instances, and the cranes also in use testify for their high cost for up-keep.

VI. Summary of Operating Cost.

Various summaries of operating cost for different plants are at hand in the literature indicated.

In his paper in the Engineering and Mining Journal Herbert Haas supplies the following estimate for a plant consisting of 20 of his units, each of which is to handle 20 tons per 24 hours. To the table he adds the cost of bedding, mixing and conveying the material, which items he says may amount to from 5 to 20c. per ton.

COST PER TON OF SINTERING WITH 400 TON PLANT

Fuel and Labor.

Fuel for primer, 1 per cent. on charge, @ $2.50 per tone	$0.025
Six men for priming, two per shift, @ $2.00	0.03
One and one-half man per unit, @ $2.00	0.15
Six crane men, @ $2.50, Three crane operators, @ $3.00	0.06
Three foremen, @ $4.00	0.03
Six laborers, @ $2.00	0.03

Power.

50 hp-hours per unit for air @ 1c	0.025
800 hp-hours for crushing sinter @ 1c	0.02
600 hp-hours for operating crane @ 1c	0.015
Crusher repairs, wear and tear, supplies, etc	0.03
Repair of plant, wear and tear, supplies, etc	0.10
Amortization: 10 per cent. on $8,000 per unit	0.11
Interest on invested capital, 5 per cent. on $8,000 per unit	0.055
Total estimated cost of sintering per ton	$0.680

Ingalls, in 1906, estimated the cost of pre-roasting in the H. & H. process to be 63c. per ton, estimating details as follows:

Labor: 3 men at $2.50	$7.50
Coal: 18 tons at $2.00	36.00
Power	3.35
Repairs	3.35
Total	$50.20 for 80 tons, or 63c. per ton

He estimates the cost of converting thus:

Labor: 3 foremen at $3.20	$9.60
9 men at $2.50	22.50
Power: 21 hp. at 30c	6.30
Supplies, repairs and renewals	5.00
Total	$43.40 = 60c. per ton of cha

Total cost of treatment Ingalls also gives as follows:

Crushing, 1.0 ton at 10c	$0.10
Mixing, 1.0 ton at 10c	0.10
Roasting, 1.0 ton at 63c	0.63
Delivering, 1.1 tons to converters at 12c	0.13
Converting, 1.1 tons at 60c	0.66
Breaking, 0.9 ton at 60c	0.54
Total	$2.16

Ingalls also remarks that the Savelsberg process will probably be a serious competitor insomuch as the roasting is omitted, thus making the process cost 63c. less.

In the same paper the cost of the Carmichael-Bradford process is given to be as estimated by the patent owners:

Labor reckoned at $1.80 per 8 hours, gypsum to cost $2.40 per 2,240 lb., and coal at $8.40 per 2,240 lb.

0.25 ton of gypsum	$0.60
Dehydrating and granulating gypsum	0.48
Drying mixture of ore and gypsum	0.12
Converting	0.24
Spalling sintered material	0.12
0.01 ton coal	0.08
Total	$1.64

In 1910 Hofman gave the cost of the blast-roasting at Midvale, Utah, as $1.25 per ton when treating 320 tons a day. He also says that the estimate of Ingalls of $2.16 per net ton of blown mixture should be deducted by one-third for Rocky Mountain plants and by one-half for the Mississippi Valley region. This would leave his estimates $1.44 for the first and $1.08 for the second case.

In this same paper Hofman states that at Salida, Colo., a Dwight-Lloyd machine is treating 50 tons of mixture a day at a cost of 75c. per ton, also that two machines in Illinois are treating 100 tons a day at a cost of less than 50c per ton.

In 1908 Austin, in the *Mining and Scientific Press*, estimated the cost for a 50-ton H. & H. plant to be:

13 men at $2.50	$27.34
1 foreman (part)	1.40
Fuel, soft coal, at $1.55	9.30
Power, est	3.00
Light, est	0.40
Repairs and supplies	2.50
Total	$43.94

and compares this at a cost of $1.02 per ton (the product weighing 15 per cent less than the raw ore) with a cost of $2.60 for hand roasting and briquetting the same material.

Huntington and Heberlein, in their paper, conclude that pre-roasting cannot cost more than 25c. a ton, and that, in the United States, where pre-roasting is more desirable than in Europe, it will cost 24c. a ton less than direct blowing.

In this discussion the cost of H. & H. treatment has been given as:

200 ton capacity	85c. per ton
same plant, 400 " "	69c. " "
and converter stall treatment as	
270 ton capacity	78c. per ton
same plant, 350 " "	68c. " "

In each case this refers to per ton product and to operating cost only.

To summarize for a down-draft plant, in particular for a Greenawalt pan installation, with even less than customary capital outlay, operating cost:

300 tons capacity—

Preparing charge	$0.06
Roasting	0.10
Crushing and loading	0.04
Limestone to cover grate	0.02
Igniting	0.05
Power	0.12
Supplies	0.02
Repairs	0.05
Total	$0.46 per ton of product

Chicago, November, 1911.

The Teaching of Technical German in Engineering Schools.

By Frederick Wm. Scholz.

Considerable attention has been paid within recent years to the teaching of engineering subjects in technical schools with the idea of obtaining greater efficiency and giving the students the best instruction. Very little has, however, been done in the matter of teaching modern languages to engineering students, so that at this time that phase of the technical curriculum is neglected in most engineering schools. It is the purpose of this article to enter into the questions involved in the teaching of modern languages, particularly German, to engineering students, and to suggest methods of solving this important problem.

The first question which we have to discuss is the need of foreign languages, especially German, to the engineer. The rapid and phenomenal progress of engineering in America and Europe has resulted in the publication of a vast amount of literature, published in form of periodicals, textbooks and pamphlets. This covers every field of human achievement, and comes from America, England, France, Germany and Italy, principally. While the literature of England gives us no trouble linguistically, that of France and Germany offers quite a different proposition.

German engineering literature, especially, is among the most valuable published in any country, not excepting the United States and England. To prove this assertion let us take a short glance at German achievement in the engineering field. The Königliche Materialprüfungsamt at Gross Lichterfelde is acknowledged to be the best testing station in the world. The Zeitschrift des Vereins Deutscher Ingenieure, published by the German mechanical engineering society stands foremost in the ranks of engineering periodicals. No society publishes such extensive and accurate papers on tests and investigations on engineering subjects, as this one in the reports called "Mitteilungen über Forschungsarbeiten." Similar conditions hold true in the field of electrical engineering, mining and chemistry. An important point in the wonderful industrial advance made by Germany is the support given to research and investigation by the government, the universities, engineering schools and business corporations. The professors of engineering at the schools, the engineers in the service of the great corporations are encouraged and aided by the government and engineering societies to engage in research work, and as a result we have German engineering literature filled with the valuable results obtained by these men.

Another point which makes German such an important language is the fact that it is not only the language of Germany, but also that of Austria, Switzerland and even non-Germanic countries like Belgium and the Netherlands. The important engineering works of France, Belgium, Italy, in fact of all of Continental Europe, are usually translated first into German, and any large engineering project is bound to have one or more German engineers among the staff, who report the progress of the work in the German engineering press. The result is that the German engineering literature is an indicator not only of the work in Germany alone, but practically takes in all of Europe, so that the engineer, able to follow the German technical literature, keeps abreast of all the important projects going on in the whole of Continental Europe.

Very little of this literature is, however, translated into English and thus brought to the attention of our engineers. That the material is important is recognized by American periodicals, for many of them have foreign departments devoted to the abstracting and translation of foreign engineering news. The really important material, however, does not find its way into American papers, for there is so much material of value published in our own language that space for foreign news is limited. It cannot be claimed that all the good foreign material is published in our papers, for the facts do not bear out the truth of this assertion. Moreover, limitations of space permit abstracts only to be published, so that the engineer who wishes to get detailed information must go to the original source for the full report. This presupposes that he is able to read the technical German with some degree of fluency, which, unfortunately, is true only with a very small percentage of engineers. If the article is important enough to him he can have it translated at some expense and at the risk of an inaccurate translation, or else he has to do without the information.

The fault lies not, however, in most cases, with the engineer, but rather with the lack of training in modern languages in the engineering school. While some schools teach German and French, they teach it in such a manner that the student obtains no benefit from the course and is glad to be relieved of further study in that field. Some schools do not teach modern languages at all and rely on the preparatory schools to furnish the necessary equipment. As a result the foreign engineering literature, especially German, is a closed book to the engineering student, and he has to rely on secondary sources to obtain his information. The remedy lies plainly at the door of the school, and we now come to the methods to be used in teaching technical German in the engineering school.

The first point is the ultimate end to be obtained. The final aim is to enable the coming engineer to read a German technical paper with such a degree of fluency that he can determine whether the article in question is suitable for his purpose and then obtain the desired information from the same.

The aim is not to teach the man how to speak German, for comparatively few of them go abroad; and if they do, they will learn more German in one year than they will learn in school in four years. It is, therefore, false to apply the methods used to teach men how to speak German to the teaching of engineering students. Two or three years of this type of instruction may, indeed, give them some slight command of the language and a little reading ability, but it will not teach them the technical literature and the vocabulary they need to read this. The course should be arranged in such a way that the student, after two or three years of German instruction, is able to read any technical paper in his particular line with some speed and with a slight use of the dictionary.

The next question is the accomplishment of this purpose. If we are able to arouse the interest of the student and show him the usefulness of the foreign language we have achieved quite a little, for if the student is interested in his work he will make an effort to advance. If he sees that the language is a tool which is useful not only in the far-off future, but at the present time, he will overcome the dislike shown by most engineering students to languages and apply himself to the task set before him.

The first step in this direction is the use of proper textbooks in the teaching of the language. Comparatively little grammar is needed for the reading of technical German, and a half year or one year, at the most, of grammar will be sufficient to meet the requirements. The grammar should not be taught separately, however, but should accompany the reading of technical literature, running parallel with the latter, till the students are thoroughly familiar with the necessary grammatical constructions. A short German grammar of good standing will suit the purpose.

The more important problem is that of the reading matter. There are various scientific readers on the market which are used in some of the schools teaching languages to the engineering student. None of these meet the need, however. First of all, they are only makeshifts, made up of articles picked up here and there; and, secondly, they do not, as a rule, use the language of the engineer, but rather that of the physicist, the theoretical chemist, the mathematician, whose language is not that of engineering literature. The student, moreover, sees no difference between this textbook and any other German reader and is likely to do only grudging work with the same.

The best method would seem to be the reading of the current engineering journals published in Germany and sent to the engineering school from abroad. Take the current engineering journals published in the various branches of engineering, place them in the hands of the students and their interest will be immediately aroused, for here they have the actual literature of the country and the information they get is that of the practical engineers at work in the field. Of course, careful selection must be made in the periodical literature, and easy reading matter, which can be found without difficulty, should be read before the more difficult theoretical material is attacked. The idea is, then, to start the reading of technical papers in the first year, beginning with the easier papers and gradually working up to the more difficult ones.

The objection might be raised that before the student is able to read the papers he should first get some sort of a working vocabulary by reading easy, common-day experience stories. We must remember, however, that technical literature is obliged to use the common, every-day words just like the other reading matter, and that the student will get this vocabulary along with the technical expressions. If we read other extraneous matter first, we will give him quite a number of useless words, which he will have to discard and forget when he comes to the reading of technical literature. Why not, then, give him the right literature at the start and have him get that vocabulary at once, which he will use all his life in the pursuit of his profession and from which he will not need to drop any words as useless.

After two years of technical German reading, giving three periods a week, the classes should be separated into several divisions, depending on the line of work the men intend to pursue in later life. The first two years should see the reading of engineering literature from electrical, mechanical, civil and some mining engineering, as also metallurgy and industrial chemistry. This would furnish the men with a vocabulary of words which occur in all of the branches of engineering, for mechanical, electrical, civil and mining engineering are, after all, closely connected in some respects, and the terms used in one line occur in another line. In the third year, after the classes have been divided into sections, each section should read those technical papers which are closely allied to their own line of future work. For example, the mining engineer might read Stahl und Eisen, Glückauf, Bergbau; the electrical engineer might read Elektrotechnische Zeitschrift, Elektrotechnik und Maschinenbau, etc. This would give the men a larger working vocabulary in their own line of work, so that at the end of the course they have a stock of words applying to general engineering and a special stock in their own line.

The work might also be made more interesting by procuring large blueprints of gas engines, turbines, valves or other machine parts and having a discussion on the constructive features, using German terms for the various parts. The use of technical dictionaries should also be encouraged. The series of six-language dictionaries of the Deinhardt and Schlomann type, covering the various branches of engineering, would furnish excellent working tools in making translations. Moreover, their usefulness would not cease after the completion of the language course, as they could be used by the men as an aid in reading the technical papers in their professional work.

The next problem is that of the instructor in technical German. Here we have to deal with a very difficult proposition, because little attention has been paid to this phase, and therefore hardly any provisions have been made to equip men for this work. We have three types of men for consideration, namely, the engineer, knowing German and English; the classical student, knowing both languages but with no interest in engineering, and the man who has command of both languages and understands something of engineering.

Take the first man, who is a trained engineer with a command of both languages. If he is going to enter the teaching profession he will likely do well to teach the engineering subject in which he is most proficient rather than the language which to him will be a secondary matter. He is, therefore, out of the question for our purpose, unless he can be induced to take up the teaching of the engineering language instead of his engineering subject. If this can be done, he would be the best man for the work, for not only does he know both languages thoroughly, but he is able to determine the right terms in case of difference between German and American terminology.

The second man is the classical student in command of both languages, but with no interest and knowledge of technology. While he may be splendidly equipped for the teaching of German literature, it is very doubtful whether he would be the right man for the teaching of technical German. First of all, he has probably no interest in engineering, and no man will do good work in a line in which he has no interest. Secondly, his vocabulary will be entirely different from that of the engineer, so that he would not have the linguistic equipment to take up this branch of teaching. Again, if he knows nothing of engineering practice and does not follow up engineering literature, he will have to rely for his translation on dictionaries entirely, which are at times inaccurate, and accuracy is one of the greatest essentials of engineering translation. If he undertakes to translate something about which he understands nothing, he cannot do justice to the work; he will only make himself ridiculous in the eyes of the students and will fail to obtain results.

It is, therefore, necessary to have men who know something about engineering, who are interested in the subject and

have complete command of both English and German. The instructor need not know how to derive a complex formula in electrical engineering, but he should know something of the practical end of engineering and be thoroughly familiar with the manufacturing processes, machinery, mechanical devices, in fact, with all the subjects with which he deals in his work. Extensive reading, a thorough command of both languages and some technical training are the essential requirements.

Doubtless there are such men with the proper training who could take up the work with success. But the constant neglect of this branch of engineering education has not brought them to the front so that we do not know at present how numerous they are and where we are to look for them. Create a demand, however, and show that in this line there is room for pioneer work for men who are willing to devote themselves to the successful solution of this important problem, and the right men will step out and take up the task. Then, when the work has been advanced to an efficient basis, introduce courses in the university curriculum, where men can be expressly trained for the purpose of teaching technical languages to engineering students. Place the man with the right linguistic equipment, with some knowledge and interest in engineering subjects, and devoted to his profession as teacher in charge of the language classes in the engineering schools, and he will transmit his enthusiasm to the students and will obtain results which will be of practical value to the student and an inspiration to the instructor.

Finally we come to the question of the amount of time to be devoted to the study of languages in the technical schools. It is a fact that the schedule of the engineering student is so heavy that it is very difficult to push in any more work. Yet, in view of the final results which would be accomplished with proper methods and the value which the future engineer will derive from the study of technical German, it seems that there ought to be room in the training of the engineer in the linguistic field.

If the time could be spared it would be well to give three years of German, divided into two years of three periods a week, and one year of two periods a week. Of course, the ideal would be four years of German, divided into the above divisions with one period a week for the last year. But if this is impossible, three years will meet the purpose to a considerable extent. This presupposes that the student had no German in the preparatory school and, of course, this makes his work very difficult. The best method would be to have the engineering schools demand two or three years of German as entrance condition, and then go on and build upon the foundations laid by the preparatory school and equip the engineering student in the special line of technical German. The fact remains, however, that the need to our engineers of a foreign language, particularly German, becomes greater each year, and that any step which will tend to bring the teaching of modern languages in engineering schools to an efficient basis will be a long step in the right direction.

Progress in Mill Design.*

By Frank E. Shepard.

Twenty years ago the Wilfley table was not known, any form of pulp classification was considered too scientific; and the cyanide solution as a solvent for gold and silver formed an interesting experiment only under laboratory conditions. But when the Cripple Creek dump ore, worth about $3.25 per ton, is treated by improved systems of milling for about $1.25 per ton, and 2 per cent porphyry copper ores of Utah and Arizona are treated with recoveries of from 70 to 75 per cent, it is time that greater attention be given the low-grade ores of Colorado, the great problem now before us. A generation ago recoveries of 50 to 60 per cent were considered good enough; to-day we must think of saving in the nineties.

Lower grades of ores must of necessity call for more complicated mill systems, and while the manufacturer is constantly striving to simplify the machinery, the mill superintendent and his men must realize that greater problems demand greater intelligence and better practical skill. If we are to accomplish these high rates of recovery there must be good team work and every man must be a friend to the system.

Consider, then, some of the methods and mechanical details by which we may raise the efficiency of our mill sysems.

Hand Sorting of Ores.

In the mill systems of Joplin, Mo., it is customary to crush the entire lot of mill ore which, in the sheet-ground districts, is composed of about 95 per cent flint gangue and about 5 per cent lead-zinc mineral. The flint gangue is very hard and in the crushing great quantities of the galena and blende must be reduced to slime with consequent loss in the mill system.

Here would seem to be a most favorable opportunity to produce higher recoveries by means of hand sorting. If the original mine ore be sorted and one-half the gangue thrown away, the sorted ore delivered to the mill bin would contain about 10 per cent mineral instead of 5 per cent in the mine run, and the volume to be treated in the mill would be reduced nealy one-half.

Much of our Colorado ore is finely disseminated and may not admit of hand sorting, but whenever possible this method of concentration should be carefully considered. Excellent designs of picking belts are furnished by a number of manufacturers and a well-designed plant may be automatic as far as the conveying of the material from mine bin to mill bin or the dump is concerned. Coal companies find it profitable to hand-pick the slate from the coal and there should be equal opportunity with the ores of precious metals. The women and children of Mexico are well known as skilful ore sorters and the patio of nearly every Mexican mine includes this branch of concentration.

Coarse Crushing.

In large mills having capacities of thousands of tons in twenty-four hours the gyratory crusher appears to be in general use on account of the large receiving-hopper capacity, the automatic feed and the absence of vibration. For smaller mills the Blake jaw-crusher is in almost universal favor owing to simplicity of its mechanism and the few parts to be renewed. An interesting development of the gyratory principle is found in the Symons gyratory crusher, which requires only one-half the vertical height of the usual gyratory design. Crusher-jaw plates of manganese, chrome and hardened steel are rapidly taking the place of the hard cast-iron or even cast-steel.

Under certain conditions the coarse crushing plant may be located at the mine. Electric power removes the obstacle of the high fuel cost at a remote station, and the reduced size of ore may be an important factor in loading and conveying details. With the possibility of hand-sorting the ore and eliminating the waste rock at the mine, the capacity of the tram or conveying apparatus could be reduced.

Uniformity of Mill Ore.

One of the most serious mistakes in the storage of mill ore is found in any plan which will not insure a uniform mixture of coarse and fine ore. In connection with the grizzly above the crusher for screening out the fine ore, there should be installed under the grizzly a chute so placed as to deliver the fine ore falling through the grizzly to a point under the discharge from the crusher, so that coarse ore from the crusher shall be evenly mixed with the fine from the undersize of the grizzly. Then the day shift will have the same ore mixture as the night shift and the mill should run steadily with little change of adjustments.

*Excerpt from an address delivered at Telluride, Colo., under the auspices of the Colorado Scientific Society, Colorado School of Mines, and Telluride Club.

With problems of a large tonnage and with ores fluctuating in grade as well as physical characteristics we may study with profit the ore bedding system in large smelting plants. The handling of large quantities of ore by automatic belt conveyors and crane systems, from suitably mixed beds of ore, might result in improved mill recoveries sufficient to warrant the increased investment.

Automatic Sampling.

The basis of all careful mill work is correct sampling, and sampling to be correct must be automatic. Messrs. Taylor and Brunton were pioneers in correct sampling methods and in their plants a system is followed of taking a one-fifth cut, recrushing this one-fifth sample, then taking another one-fifth cut of the recrushed sample, and so on—the whole sampling plant including five oscillating time samplers and crushing rolls between each sampler. In large milling systems a separate and automatic sampling plant on the lines indicated is well warranted, but in smaller mill systems the plan must be simpler. Two automatic samplers cutting a fifth or tenth sample, with a mixing cylinder between the two, will give a sample one-twenty-fifth or one-one-hundredth of the entire mill feed.

Under some conditions this sample must be taken after the ore has passed the grizzly and crusher; then it may be necessary to instal an extra elevator to give sufficient fall for subsequent mill operations. At the expense of additional installation it is certainly worth while to know the value of the ore with which we start operations. In a roll crushing plant a good position for the automatic sampling plant is just below the discharge spout of the elevator delivering the product from the coarse rolls, provided that no other than the original ore stream enters the coarse rolls.

It is even well to consider sampling the various feeds to the different mill units so that every phase of the mill system may be studied. Samplers have been designed to be controlled electrically from a master clock, so that the samples may be taken at regular intervals, or at times not anticipated by the mill operators. Such a system need not be too complicated and with reasonable care will give most valuable records.

About twenty years ago Mr. J. H. Ernest Waters, of Telluride, became interested, while in Denver, in a steam-pressure recording gauge, purchased one and had the gauge installed in his office and connected with the steam mains of the boiler plant, without arousing the suspicion of the firemen. He took records for a few days and obtained some charts with steam-pressure lines looking similar to the trail leading to Bridal Veil Basin. Then he explained the recording gauge to the firemen and showed them the records, and then followed records with a nearer approach to the circle. No doubt that pressure gauge paid for itself many times in coal saved and a more uniform steam pressure. This to illustrate the value of accurate records.

Fine Crushing.

Now we come to the parting of the ways, with advocates asking us to take various paths. At this stage of mill operation we find, in Western mills, three general systems of fine crushing:

Rolls.

Stamp batteries.

Roller mills.

For the reduction of ore from crusher product, 1½ in. or 2 in. size, down to a suitable size for coarse jig or coarse table concentration, the modern crushing roll employs the correct principle for the liberation of the mineral crystal with the least amount of slime product.

Modern crushing rolls are provided with adjustments so that the space between the shells may be changed while the rolls are in operation. Other details provide an end adjustment of the shafts to prevent beads forming on the edges of the shells. Forged steel shells are the best for modern conditions. This material may be machine-finished with special steel tools and the surface of the shells thus maintained true for fine crushing.

Modern crushing rolls, with machine-finished forged-steel shells, are used to reduce ores to a product as fine as 30 to 40 mesh, and if reasonable care be given the shells such fine crushing is possible. This means an even and regular feed across the entire face of the roll shell, and a new shell for the fine rolls whenever grooving or uneven wear appears, the worn shell of the fine roll being transferred to a coarser crushing roll. In large plants having shops a lathe may be provided to resurface the worn shells.

The tendency, however, is to use crushing rolls for products not finer than about 12 mesh, No. 19 wire, equal to 0.042 in. This 12-mesh product is about the maximum for concentrating table feed, and with the short tube mill already being established as an economical system for fine crushing, the range of roll crushing does not need to be outside the limits of, say, 2 in. maximum down to 1/24 in. minimum.

For the recrushing of jig middling rigid rolls have advantages over the spring rolls. The average size of the mineral crystal imbedded in the middling particle determines the minimum size to which the particle shall be crushed. The rigid rolls may be set to the desired size and the middling particle is crushed down to this size, and no further, the aim being to break the gangue portion away from the mineral crystal. The use of the rigid roll insures the maximum size of mineral crystal with the least production of slime.

One of the great surprises in the development of mining machinery is the strong position occupied by the stamp mill. Here is a most complicated array of mechanism, producing a chaos of noise, requiring elaborate foundations, and a large number of renewable parts, and yet the ring of the stamp goes merrily on through methods of amalgamation and lixiviation, then concentration and on to cyanide.

South African practice deals in terms of 2000-lb. stamps, and the end is not yet. Such heavy stamp weights call for massive foundations and great increase in the dimensions of mechanical parts and yet the practice appears to be commercially successful.

The use of concrete in mortar blocks is a good advance in point of construction, maintenance and capacity. Cast-steel for shoes, dies, cams, tappets and boss heads shows increased service over the former cast-iron parts. The narrowing of the mortars at the issue-level results in greatly increased capacities. The gradual change from inside to outside amalgamation reduces labor costs and loss through shut downs. Separate motor drives for battery units simplify the plan from the complicated jackshaft drives. Specifications now call for chrome-nickel steel as a material for the camshafts.

Structural steel for the battery frame is quite possible. Probably the best form of battery post is a box column filled with concrete to reduce the sound and vibrations. Designs have already been made for concrete battery posts reinforced with steel rods molded integral with the concrete mortar blocks. Sub-bases weighing about 7000 lb. give sufficient bearing area for the mortars on concrete blocks, instead of anvil blocks weighing 16,000 to 20,000 lb.

The large mills treating the porphyry copper ores have brought about a rapid development in roller mills, more familiarly known as high-speed Chilian mills. In crushing tens of thousands of ore a day certain merits must be found in this type of intermediate crushing device, but when one considers the renewal of large tires and die rings, screens, bearings, pinions and gears the query appears will this type of crushing mill endure in mills of great capacity?

Ball Mills.

The cement industry has given us the tube mill, that fine crushing device of great simplicity, and we shall yet appreciate the great value of the ball mill as a desirable intermediate crushing device, possibly supplanting roll, stamp mills and high-speed Chilian mills.

The Krupp type of ball mill is successfully used as an intermediate crusher between the coarse crushing mill and the tube mills, which grind to a final product of 100 to 200 mesh. The Krupp ball mill is cylindrical and is rotated on trunnion bearings, the feed being introduced to the inside of the cylinder at one of the trunnions.

On the inside of the cylindrical shell is arranged a series of steel shelves and perforated plates. On the outside of the cylindrical shell is a screen limiting the size of the crushed product. Inside the mill is a charge of forged-steel balls, the largest of which may weigh about 70 lb., varying down to the balls of about 2½ in. diameter.

With a suitable charge of ore delivered to the ball space, the rotation of the mill turns the mass of balls and ore over and over and the falling of the balls from shelf to shelf crushes the ore to a size which will issue through the outside screen. While the product from this mill is excellent, objection is found to the shelves and perforated plates as well as outside screens, which require renewal. If we may use the high crushing efficiency of the forged-steel balls and in some way eliminate the perforated plates and screens we may have a very simple intermediate crushing device.

Such a simple and compact crushing device seems possible. The scoop feed in connection with a spiral lining for the feed trunnion of the tube mill is a success. The device known as the tire discharge of a tube mill is a success. This tire discharge permits an opening about 20 in. diameter through which the fine crushed pulps issue. In this 20-in. diameter opening is fitted a reverse spiral so that any pebbles or large particles of ore falling into the grooves are carried back into the mill. Only the particles which have been crushed fine enough to be carried out by the current of water may issue as finished product. If, then, we design a ball mill, using the scoop feed for the feed end and the tire discharge of 20 in. diameter for the discharge end, we are utilizing two well-known and successful elements. A reasonable proportion for the ball mill would be that the diameter be equal to the length of the shell. A mill 4 ft. diameter would be 4 ft. long; a mill 5 ft. diameter would be 5 ft. long.

The liners of the feed and discharge heads may be hard iron or cast steel. The lining for the cylindrical portion of the shell should be of chrome steel or equivalent. The diameter of the balls should be between 3½ in. and 7 in. The larger the feed particle the larger the diameter of the balls.

Ore as coarse as 2 in. diameter may be fed to the ball space of the mill by means of the scoop feed. The mill is to be driven by machine-cut pinion engaging with a machine-cut gear bolted to the feed or discharge head. When the mill is rotated the mass of balls and ore are carried up to about the level of the axis of the shell and the heavy balls rolling down the slope crush the ore. Fine crushed ore issues through the 20-in. diameter tire discharge, any coarse particles or balls worn small being returned to the ball space by means of the reverse spiral inside the tire discharge.

The average results from several types of ball mills show that 1 ton of steel balls will crush about 50 tons of ore during twenty-four hours from a feed of 1½ in. diameter down to a product from 12 to 20 mesh in one operation. Using the same factor, the following table gives the sizes, capacity and power:

Diam. feet.	Length feet.	Wt. of balls in mill lbs.	Wt. of ore in mill lbs.	R.P.M.	H.P.	Capacity tons 24 hrs.
3	3	1035	207	35	7	25
4	4	3360	672	28	25	80
5	5	7650	1530	26	56	190

To compare this proposed ball mill with other types of intermediate crushers, the following table is given, assuming ore to be crushed from 1½-in. feed down to a product passing 12 mesh, No. 19 wire, or about 1 mm.

	Tons capacity 24 hours.	Total wt., lbs.	Price.	H.P.	Wt. of crushing moving parts.
6 ft. diam. Chilian....	40–50	50,000	$3,600	25	20,000
10 stamp mill 850 lbs..	40–50	35,000	2,100	20	8,500
4 ft. x 4 ft. ball mill..	70–80	20,000	1,600	25	3,500

This type of ball mill in connection with crusher and tube mill, making only three crushing units, will reduce ore from run-of-mine to slime pulps passing 150 to 200 mesh; a very simple crushing system for cyanide mills.

The ball mill makes suitable product for table feed, and then the tube mill may recrush the table tailing and middling. The consumption of steel balls amounts to about 1 lb. per ton of ore crushed when crushing dry and 2 lb. per ton of ore crushed when crushing wet.

A review by Mr. S. F. Shaw of nineteen cyanide mills in the United States and Mexico gives the following conclusion: "Jaw breakers are more favored than gyratory crushers; Dodge breakers are used in only one mill; stamps are almost universal for fine crushing; Bryan, Huntington and Chilian mills are used in a few plants as intermediate grinders following the stamps. Tube mills are being used more and more for fine grinding."

By the use of a ball mill following a Blake crusher run-of-mine ore may be reduced to jig or table pulps in two crushing operations without any screens in the mill system. The small number of mechanical parts; the small mill space occupied; the great range of products which may be produced with simple adjustments; the absence of screens; the crushing of dry ore as well as wet, and the high capacity per unit weight of wearing parts are strong factors for the use of the ball mill in the intermediate crushing operations of our Western mills.

In designs for cyanide mills the diameter of the ball mill and the tube mill might be the same, so that the feed and discharge head castings could be interchangeable between ball and tube mill. The shell lining is bolted to the shell and the large tire discharge opening permits the changing of lining without removing any manholes.

The Gröndal system for the concentration of iron ores uses a ball mill along these general lines, but the feed device is more complicated, and the discharge is through a trunnion bearing. The proposed tire discharge allows a larger and freer discharge as well as a convenient means for renewing the steel liners.

The Hardinge conical mill is a good type for ball mill crushing and has been successful in several installations for intermediate crushing. The Blake crusher and Hardinge conical ball mill followed by the long cylindrical tube mill makes a good combination for cyanide mills in crushing to 150 or 200 mesh.

Coarse Concentration by Jigs.

Concentration by jigs includes sizes of feed as coarse as 2½ in. diameter down to sizes as fine as about 12 mesh, No. 19 wire, or about 1 mm. diameter. Formerly finer pulps were concentrated on jigs but since the advent of the reciprocating table, ore pulps finer than 1 mm. are treated on the tables.

The Butte copper ores are jigged as coarse as about 2½ in. diameter, and the rich pieces of ore, including chalcopyrite, chalcocite, enargite and bornite, are subjected to a heavy jigging action with the result of excessive attrition and liberation of a considerable proportion of slime which causes considerable difficulty in subsequent mill operations. Such coarse jigging of friable ores might be replaced by improved systems of picking belts and thus prevent the considerable loss through formation of slime by attrition. Power and water are consumed in large quantities in such heavy jigging operations, and the machinery details need to be very heavy.

When the jig feed is smaller than 1 in. diameter the power and amount of water used are greatly reduced. The average sizes of jig feed in American practice probably lie between 1 in. diameter and 1/32 in. diameter.

Without doubt the jigging of ores is one of the most interesting and the most complicated of milling problems, combining as it does the study of the crystalization of minerals, specific gravity, cleavage, planes, relative hardness of mineral

and gangue, distribution of mineral contents in the gangue matter, association of minerals of nearly equal specific gravities, and endless combinations which often present baffling problems. Added to these questions are the various jig adjustments referring to stroke, speed, depth of bed, number of jig compartments, relation of screen aperture to feed particle, and combinations varying with each ore, all requiring careful and persistent study.

The familiar type of Harz jig found in our western mills consists of one to four compartments, or more—each compartment being 18 to 20 in. wide and 24 to 40 in. long. This Harz jig, under average conditions will treat about 1½ tons of feed per square foot of jig screen area per day of 24 hours. The large jigs of the Joplin district are often found with seven compartments or cells, each compartment having an area of about 20 sq. ft., or a total of 140 sq. ft. of jig screen area. These seven compartment Joplin jigs treat at the rate of 700 tons per day of 24 hours, or 5 tons of feed per square foot of screen area. The Hancock jig, the feature of which is the movable screen, is a successful type for large capacities and will treat about 10 to 15 tons of feed per square foot of jig screen area daily.

All these jigs employ both a pulsion and suction cycle of water through the jig screen. The average water consumption for Harz jigs in American practice is about 4700 gal. of water for every ton of ore treated. The Hancock jig uses from 350 to 800 gal. of water per ton of ore treated; a very low water consumption.

A few years ago a series of tests on the Richards pulsator jig showed in practical mill operations that 1 sq. ft. of screen area will treat 100 to 180 tons of ore in 24 hours as compared with:

Harz Jig, 1½ tons feed per square foot of screen area.

Joplin Jig, 5 tons feed per square foot of screen area.

Hancock Jig, 10–15 tons feed per square foot of screen area. This high rate of the Richards pulsator jig is made possible by the use of a pulsion stroke only. In the earlier designs the ore bed was 10 to 14 in. deep, requiring about 30 ft. head of hydraulic water at the rate of 1000 to 1200 gal. per ton of ore treated.

The later designs make use of an ore bed of but 4 or 5 in. deep and a consequent reduction of the head of hydraulic water to 10 or 15 ft. This reduction of hydraulic water head has reduced the consumption of water to 600 or 700 gal. per ton of ore treated, or about one-seventh the amount of water required in Harz jigs. The latest types of Richards pulsator jigs also have separate pulsator valves for each compartment, thus giving accurate and wide ranges of adjustment to suit different conditions of ore treatment. Dewatering devices are also placed between the compartments to allow closer and more complete separation between minerals of slight difference in specific gravity. While the theory of this pulsator jig is based on a screen-sized feed, yet in practice a rather wide range of sizes is permitted. The concentrates are particularly clean with a minimum of attrition from wear of concentrate particles in the jig bed. The Richards jigs at the Lewis Mine, Telluride, deliver concentrates ranging from 65 to 70 per cent lead. In the Bonanza mill, Saguache County, lead concentrates are produced as high as 79 per cent lead. In the Cobalt district, Canada, Richards jigs are making concentrates of the smaltite and niccolite ores running as high as 4000 oz. of silver to the ton. A jig installation in Sonora, Mexico, produced argentite concentrates running 400 to 500 oz. of silver per ton. Low grade iron ores of 40 to 45 per cent have been enriched to 65 per cent iron.

There is no doubt about the favorable application of this pulsator principle to a wide range of ores. The numerous mechanical details of the Harz jig are replaced by an extremely simple rotating valve requiring a small amount of power and lasting through a long time of service. In several designs of Harz type, great attention has been given to mechanical elements which shall give a pronounced pulsion stroke *up* through the screen and diminish as much as possible the suction stroke *down* through the screen. This differential motion, so-called, is found to give a greatly increased capacity and also reduces the blinding of the jig screen. A study of the elements of mechanism to produce such differential motions will show complication and the necessity for constant attention to adjustments and renewals for wear. The very simple mechanism of the Richards pulsator valve, consisting of but one moving part and entirely automatic action gives this pronounced pulsion stroke with no suction whatever. The recent design having separate pulsator valves for each jig compartment gives additional automatic features allowing any possible jig adjustment.

Pulp Classification for Concentrating Tables.

Considerable progress has been made in the application of important principles in the classification of ore pulps previous to table work, but there is much more to study and to do before we reach the reasonable efficiency. Does it pay to consider all these additional devices designed to produce higher recovery? Assume a mill of 100 tons capacity during 24 hours; the crude ore runs $10 per ton; the mill makes a recovery of 70 per cent. Suppose by the addition of some device an increased recovery is obtained, say 75 per cent instead of 70 per cent. This means an additional creation of value to the amount of $18,250 per year. In an ore worth $5 per ton an increased recovery of 5 per cent means an additional saving of $9,125 per year.

The preparation of fine pulps previous to table concentration involves two general systems; one based on the screen sizing of pulps, producing grains of nearly uniform diameter, and the other known as the hydraulic classification of pulps in which the mineral grains are small and the grains of gangue comparatively large, or the result of equal falling grains of mineral and gangue in a still body of water or an upward current of water. As mill systems increase in capacity the mechanical difficulties found in maintaining fine screening systems become too great and so the tendency is toward the application of the hydraulic principles of classification.

To Dr. Robert H. Richards is due the great credit for the many practical applications of hydraulic classification; for if one will study the results of his 40 years of investigation it will be found that the most successful hydraulic classifiers of to-day utilize some feature developed by him.

The hindered settling design as well as the Richards-Janney are developments of the earlier design known as the vortex classifier.

The Richards pulsator classifier is successful in the classification of a wide range of ores. Recent designs have reduced the number of parts to adjust, so that now only one water-gate valve requires adjustment, whereas in former designs separate water valves were placed on each of the six compartments. The gates between the compartments also have been removed and the adjustable concentrate-discharge gates have been removed, and in their place are spouts which require but one preliminary adjustment.

The use of the screen in this type of classifier has resulted in the saving of high grade shipping products direct from the classifier, but under some conditions of water supply, difficulties are found from the screen blinding and so recently there has been developed a type of classifier utilizing the many favorable features of the pulsator water current and doing away entirely with the use of the screen. This improved form is known as the launder type of pulsator classifier and this design permits the use of any number of pulp classifications to suit the requirements of the mill system.

An ordinary wood launder is used running above and near the feed end of the concentrating tables. Separate sorting columns are provided for each table, being bolted to the bottom of the wood launder, with a separate pulsator valve for each sorting column so that each table may have its own particular adjustment. The only adjustment to make in this

launder type classifier is to determine the diameter of opening in the wood spigot at the bottom of the sorting column.

A novel device for cencentration is permitted, in the use of a pulsator jig compartment, which is bolted to the bottom of the wood launder the same as the classifier units. This launder jig has a separate pulsator valve but no concentrate-discharge gate to adjust. A screen is used in the jig compartment and the concentrate discharges down through the screen into the hutch and out through the opening in a wood plug at the bottom of the hutch. The discharging of the grains of free mineral through such a launder jig relieves the coarse tables from a considerable burden and reduces the amount of middling product delivered from the coarse table.

Dewatering Devices.

Great improvements over former methods have been made in the development of systems for dewatering pulps and slimes. Too often pulps are delivered to the concentrating tables in too dilute a condition with a consequent loss.

The dewatering of pulps becomes a very important point in the feed to tube mills, for it has been demonstrated that a feed pulp containing about 40 per cent moisture gives the best efficiency in tube mill crushing. In South African practice the Caldecott diaphragm cone is reported to give satisfaction in large installations where large cones may be employed and the mill feed is fairly constant. However, in small mills with fluctuating loads difficulties in adjustment may be met.

The dewatering of jig and table feed-pulps insures a larger capacity and more complete separation of the various products. Slime table work is particularly sensitive to the consistency of the pulps fed to the tables; for a thickened slime pulp is quite necessary for successful recovery. In districts with low or fluctuating water supply the recovery of water from tailings pulps for use again in the mill system becomes a serious necessity. The Tomboy mill in Telluride makes use of a filter plant for the purpose of reclaiming water from the tailings and furnishes clear wash water for the concentrating tables. The Miami mill in Arizona has a very extensive plant of cement settling tanks returning about 75 per cent of the tailings water for use in the mill system.

A serious fault in many mill systems is the great volume of wash water used to sluice the material through the mill. In many cases the use of too flat launders requires extra wash water, which is carried over the jigs and tables. In such cases, the surplus volume should first be eliminated by means of suitable dewatering devices. Mr. Philip Argall, at Stratton's Independence mill, Victor, Colorado, uses a double spiral classifier of his invention for the purpose of dewatering tailings sluiced from the mill, and uses the reclaimed water for further sluicing operations.

Tube Mills.

Great progress is being made in the design as well as the operation of this excellent device for the fine crushing of pulps. The tube mill appears to be the most efficient means for the final reduction to slime previous to agitation in cyanide mills.

The use of the scoop feed has overcome the former troubles from wear of packing joints. This simple and automatic feeder receives general endorsement. The spiral lining in the mills using the trunnion feed insures a positive feed to the pebble space of the mill. The heads are usually lined with hard iron plates, and in the trunnion type mills the lining is swelled out around the feed and discharge openings to divert the falling pebbles away from the heads, thus allowing freer entrance and discharge of pulps.

Silex or natural flint linings 4½ and 6 in. thick are used, as well as the hard cast-iron ribbed linings of the El Oro type and other similar designs. The Brown sectional hard iron and manganese lining give good success in Australian practice. The use of machine cut gears on tube mills was first advocated and used in Colorado and now the practice is quite general.

The design known as the tire and trunnion type offers advantages in a large diameter discharge-opening about 20 in., which allows greater capacity and permits more ready access to the interior of the mill. The tire discharge-opening is bushed with a heavy hard iron reverse spiral, which carries small pebbles or oversize pulp back into the pebble space of the mill, only the slime pulp floating out with the water through the discharge-opening. Provision is made for changing the level of discharge for the regulation of pulp sizes, by varying the diameter of the tire discharge-opening.

Tube mills are in successful operation for the recrushing of jig and table middlings for further treatment on fine and slime concentrators. In the Lewis Mill, Telluride, a 4-ft. diameter by 10-ft. long trunnion type tube mill regrinds the coarse table middlings from a 60-ton mill-feed, in 24 hours. At the Bingham Junction, Utah, mill of the United States Smelting, Refining and Mining Company, a 5-ft. diameter by 14-ft. long tube mill, trunnion type, recrushes jig and table middlings at the rate of 136 tons in 16 hours, or 204 tons in 24 hours, delivering a product passing a 40-mesh screen with but 10 per cent of the pulp finer than 200 mesh. This tube mill may be used to produce a granular pulp with but a small percentage of slime for subsequent table work, as well as slime pulps for cyanide practice. The tube mill is a remarkable all-round machine for fine crushing and there may be further developments which will serve well in our mill systems.

Here, then, are a few points of interest in the progress of mill design. The subject is great, and fast multiplying into many branches of marked importance. In spite of what we may desire, our mill systems for the treatment of more complex or lower grade ores, must of necessity require additional devices to care for them; and then a greater intelligence and skill on the part of the operators, and a hearty co-operation between designer, manufacturer, mill superintendent and the man on the mill floor.

The manufacturers always appreciate the helpful suggestions of the men who are in the thick of the mill work, and will do their best to return in good measure improvements in machinery details which will make necessary adjustments easier for the mill man, and renewals and repairs as small as possible.

Denver Engineering Works Co.,
Denver, Colo.

The Assay of Ores Containing the Platinum Group of Metals.

By A. C. Dart.

In Metallurgical and Chemical Engineering, February, 1911, page 75, there appeared an article on the concentration of platiniferous copper ore at the Rambler Mine, Wyoming. The article contained a brief statement of methods of assay and analysis used in obtaining the results there given, with due recognition of the fact that the methods were incomplete and that the results might, therefore, be open to some question.

As a matter of fact, it was impossible at that time to make use of commercially accepted methods because they were not available; and it was not until some months later that the writer secured, from various sources, information regarding commercial methods.

The following procedure was finally adopted for the assay of platinum-bearing ore and concentrate produced at the Rambler Mine, and formed the basis of settlement of a number of shipments. For other classes of material certain changes would be necessary in the method of obtaining the first button. Suitable quantities of ore or concentrate are taken, depending on the richness of the product.

Eight portions of one assay ton each are fused with a suitable flux in 20-gram crucibles. If considerable copper is present, as in Rambler ores, the resulting lead buttons are scorified until soft and then cupelled.

The precious metal buttons obtained by cupellation are weighed, giving the total quantity of precious metals in the ore. They are then combined in two check lots, representing four assay tons each, and re-cupelled with ten times their weight of pure silver. The resulting buttons are then parted separately with 12 per cent nitric acid, and finally with concentrated nitric acid in test tubes placed in boiling water. Silver, palladium, and platinum are thus dissolved, and gold remains. The residue is washed by decantation in the usual way, ignited, and weighed, giving the quantity of gold contained in four assay tons of pulp.

The nitric acid solution obtained from the foregoing step is kept as small in bulk as possible. Hydrochloric acid is added to precipitate the silver as chloride, which is filtered and washed. The precipitate may be reserved for a future check.

The filtrate from the silver precipitation is then evaporated to dryness. The residue is moistened with a few drops of hydrochloric acid and taken into solution with 10 cc hot water. The solution is allowed to stand for half an hour, and if silver chloride separates it is again filtered and washed, the precipitate being combined with the first silver chloride obtained.

The filtrate is now made ammoniacal, then acidified with formic acid and boiled. This will precipitate metallic platinum and palladium. Usually no precipitate forms until after boiling begins, and ebullition should be continued for half an hour. The precipitate is filtered, washed, and ignited. The weight gives the combined quantity of platinum and palladium.

After weighing, the platinum and palladium are converted to chlorides by dissolving in aqua regia, evaporating to dryness and taking up with a few drops of hydrochloric acid and 50 cc hot water. This solution is saturated with pure, crystallized ammonium chloride; 10 cc alcohol is added, and the whole allowed to stand for not less than 24 hours. The precipitated ammonium platinic chloride is then filtered, washed with a saturated solution of ammonium chloride, and ignited very slowly on account of the possible volatilization of the precipitate. The resulting metallic platinum is then weighed.

By this method gold and platinum are determined directly. Silver is determined by difference between the weight of the original buttons, and the combined weights of the gold and precipitated platinum and palladium. Palladium is determined by difference between the combined weight of platinum and palladium, and the platinum precipitated by ammonium chloride. A direct determination of silver may be made on the chloride precipitate if desired.

Calculation of Furnace Charges—IV.

By Regis Chauvenet.

Some illustrations of the application of stoichiometric principles to problems cognate to smelting were promised, and are here inserted, to serve as types of method rather than of practical cases. They contain, nevertheless, useful demonstrations of the facility with which a small knowledge may be applied. Problems not dissimilar are often presented in practice and may be solved by application of the same elements.

(a) A zinc concentrate containing 90 per cent of zinc sulphide and 10 per cent silicious gangue, is roasted, being converted into a mixture of zinc oxide and zinc sulphate (ZnO and $ZnSO_4$). It now assays 45 per cent zinc. Find, (1) weight of the product, original concentrate having weighed 100 lb.; (2) weights of the ZnO and $ZnSO_4$ in the roasted material.

Solution.—Taking atomic weight of zinc as 65, the percentage of zinc in the original material was 60.3. This is 45 per cent of 134, answering first part of the question. For the zinc remains the same in weight, as does the gangue. Weight of product 134 lb.

To ascertain the respective weights of the two compounds, it is easiest to refer to the actual weight of the zinc contained, i.e., 60.3 lb.

Per cent of zinc in $ZnSO_4$ is 0.4037. Per cent of zinc in ZnO is 0.8025 (that is, taking unity = 100 per cent).

Let x = weight in lb. of the $ZnSO_4$. Then $124 - x$ = weight of the ZnO (for since the gangue weighs 10 lb., the zinc salts weigh 124 lb.).

We have then: $0.4037\,x + 0.8025\,(124 - x) = 60.3$

Hence, $x = ZnSO_4 = 98.32$ lb., and ZnO = 25.68 lb.

Proof. $25.68 \times 0.8025 = 20.608200$

$98.32 \times 0.4037 = 39.691784$

Sum = 60.299984 or 60.3 lb.

We have seen problems identical as to principle of solution declared to be too troublesome to bother with, by practiced men.

To repeat the substance of a remark made early in this series, chemical relations, easy to understand and apply, having never been properly inculcated, or their elements having "rusted," a singular mystery has been flung over all such problems, slag calculation included, which a little serious study would dispel forever.

(b) The following exercise, somewhat fanciful as to data, is given merely for verification by anyone sufficiently interested in the applications of stoichiometry to work it out. As in (a), albeit this particular problem is of no practical bearing, its solution will aid in working out many simpler questions of quite similar data and method.

An ore has the following analysis: (assume 100 lb.)

SiO_2	31.48 per cent				
FeS_2	30.00 " "	Fe	14.00	S	16.00 per cent
PbS	19.12 " "	Pb	16.56	S	2.56 " "
ZnS	19.40 " "	Zn	13.00	S	6.40 " "
	100.00			Total sulphur =	24.96 " "

This ore is roasted until it contains no more sulphides, losing 10 per cent of its lead and 20 per cent of its zinc in fumes.

All of the iron has now become Fe_2O_3. One-half of the remaining lead goes to PbO and one-half to $PbSO_4$. One-third of the remaining zinc goes to ZnO and two-thirds to $ZnSO_4$.

What is weight of the roasted product?

What is summation analysis of same?

Solution. Open a debit and credit account, setting losses against gains in accordance with the conditions specified. Gains are all in oxygen.

Methods having been given in our "Chemical Introduction," we here simply tabulate the results, distinguishing between oxygen in oxides and in sulphates.

Losses.	lb.	Gains.	lb.
FeS_2 loses S_2	16.000	O (in Fe_2O_3)	6.00
PbS loses 1/10 of Pb	1.656	O (in PbO)	0.576
PbS loses 1/10 of S	0.256	O_4 (in $PbSO_4$)	2.304
PbS loses ½ of 9/10 of S	1.152		
ZnS loses 2/10 pf Zn	2.600	O (in ZnO)	0.853
ZnS loses 2/10 of S	1.280	O_4 (in $ZnSO_4$)	6.826
ZnS loses 1/3 of 8/10 of S.	1.706		
Total loss	24.650	Total gain	16.559
Subtract gain	16.559		
Net loss	8.091		

Original weight 100 lb., present weight 91.909 lb.

Composition (lb.) of product:

SiO_2	31.480	per cent
Fe	14.000	" "
O (in Fe_2O_3)	6.000	" "
Pb	14.904	" "
$O + O_4$ (with Pb)	2.880	" "
S in SO_4	1.152	" "
Zn	10.400	" "
O + O_4 (with Zn)	7.679	" "
S in SO_4	3.414	" "
	91.909	" "

Analysis of same:

SiO_2	34.251	per cent
Fe	15.232	" "
Pb	16.216	" "
Zn	11.316	" "
S	4.968	" "
O	18.016	" "
	99.999	" "

Summation analysis by compounds:

SiO_2	34.251	per cent
Fe_2O_3	21.760	" "
PbO	8.735	" "
$PbSO_4$	11.868	" "
ZnO	4.701	" "
$ZnSO_4$	18.670	" "
	99.985	" "

(c) An iron ore has 88 per cent Fe_2O_3 and 0.8 phosphoric anhydride (P_2O_5). In smelting it produces, with its fluxing material:

1. Pig metal whose analysis shows in part:

Carbon	3.00	per cent
Silicon	2.80	" "

Pig metal also contains all of the phosphorus, reduced from the P_2O_5 of the ore (take atomic weight of phosphorus at 31).

2. Slag, whose weight is one-fifth of the weight of the ore charge, and which contains 3 per cent of iron oxide (FeO) derived from the ore.

What weight of the ore produces 100 lb. of the pig metal? What is the completed analysis of the pig metal?

Answer. Weight of ore which produces 100 lb. pig = 153.2 lb.

Analysis of the pig metal:

Iron	93.66	per cent
Carbon	3.00	" "
Silicon	2.80	" "
Phosphorus	0.54	" "
	100.00	" "

Mixing Ores for a Given Percentage.

It is sometimes necessary to mix ores or other material, so that the mixture shall contain a certain percentage of a given substance. Calculations for a furnace charge start, of course, from the analysis of the mixture.

The formulation of this little problem is readily translated into the following:

Rule. Take weights of the ores in inverse ratio to the differences between their assays and the (required) assay of the mixture.

Example. (a) Mix two ores containing respectively 40 and 8 per cent of a certain constituent, so that the mixture shall contain 16 per cent.

No. 1. The larger per cent. less the required per cent. is $40 - 16 = 24$.

No. 2. The required less the smaller per cent. is $16 - 8 = 8$.

Now take weights of the two ores inversely as these figures, i.e., take 8 parts of No. 1 and 24 parts of No. 2 (or in this case, reducing to simpler ratio, 1 part of No. 1 and 3 parts of No. 2).

Proof:

100 parts of No. 1 contain	40 lb. (parts)
300 parts of No. 2 contain (3×8)	24 lb.
400 parts of the mix contain	64 lb.

And 64 is 16 per cent. of 400 as required.

If we have three lots, there is no definite solution. The problem is indeterminate, unless there are but two lots to be mixed, since the required percentage must fall either between No. 1 and No. 2 or between No. 2 and No. 3.

We may, however, by limiting weight of one lot to a certain figure, or by stipulating a certain proportion as between certain classes of ore, reduce the problem to a determinate one. Cases of this kind are exceptional, but it is well to have a ready method of figuring on them.

(b) Three ores assay respectively 39, 24 and 8 per cent of a certain constituent. We want 16 per cent in the mixture. We must use both 1 and 2 and the latter in twice the quantity of the first. Assume for convenience 100 lb. of No. 1.

100 lb. of No. 1 contain	39 lb. of substance
200 lb. of No. 2 contain	48 lb. of substance
300 lb. of the mix contain	87 lb. of substance

The "mix" then of 1 and 2 contains:

$$\frac{87 \times 100}{300} = 29 \text{ per cent}$$

Now combine the "mix" with ore No. 3 as in previous example.

Method of Representative Equations.

All methods in common use hitherto have depended upon one or the other of two procedures. In the one, adjustment of matte and bases having been made, if necessary, the preestablished ratio of acid to base is applied by the use of "excess," whether chemical or arithmetical, according to formula asked for. In the other, after the same preparation, formula is ignored, at least in form, and a given ratio of constituents, sometimes confined to that of silica to bases, sometimes of silica plus alumina to bases, often also of bases to one another, is sought.

It has been pointed out that many "type" cases, which are usually stated in percentage form, were in fact originally derived from formulas. In our last article (No. V) we shall touch upon such cases, showing at the same time how a calculation may be made for them without getting the formula into the conventional analytical form.

There are variants in method, in the above named two procedures, into which we do not propose to go. They all depend at last upon some application of the "excess," and it is the main object of this series to show that complex cases are the ones which should drop all use of the excess calculations.

It has already been noted that the problem is easy when there is but one fluxing material to be added, complex when there is more than one. It is often imperative to use two fluxes, and whenever this is necessary it is almost invariably the case that a ratio between bases is needed.

The "bases" range themselves into the "iron" and "lime" groups, as already explained. Let us further explain, that in the type examples, (a) to (e) with which we set forth the general method, we clear ourselves of complications at the outset, by tacitly assuming that matte has been "taken out," also that all adjustments of bases have been made. Thus, we present but two bases, viz.: iron and calcium. Furthermore, these are examples of a method, not of type slags. If a method of computation is correct, it makes absolutely no difference, so far as understanding it is concerned, whether the case is common, or exceptional, or even whether it is probable. If the reader can work one case, in the arithmetical or algebraic sense, he can work as well with any other data.

Notwithstanding the fact that the "Equation" method is more applicate to complex cases, we simplify a first exposition by selecting problems of no complexity whatever.

It must be clearly understood that the method is equally applicable to formulistic or percentage slags, but that the formula, *once translated into either ratio or percentage,* no longer figures in the calculation.

How to make such transformations has been shown in the "Chemical Introduction," but it is a matter familiar to any chemist or metallurgist.

Examples. (a) Given an ore, whose fluxing constituents are as follows:

Silica	35.00	per cent
Iron oxide (FeO)	20.00	" "

The only fluxing material is a limestone whose analysis is:

Silica ..... 10.00 per cent
Lime (CaO) ..... 50.00 " "

Take here, as in all the other problems to follow, 100 lb. of ore.

Requirement for the slag, Silica 40 per cent, bases 60 per cent.

Call weight of limestone to be used $100x$.

Since we use 100 lb. as basis of calculations, any numerical expression will denote either pounds or percentage, reckoning on the ore.

The use of "$100x$" instead of "x" will presently be seen to simplify the statement.

Since $100x$ is weight in lb. of the limestone, $10x$ must be the weight of its silica and $50x$ the weight of its lime (CaO). That is, if we write analysis of our flux as usual in analytical form, i.e., in "parts in 100" it is evident that by taking as coefficients of x the percentages in that analysis, we have, if we call the whole weight "$100x$" correct expressions at once for each constituent. Hence the name we give the method, "representative equations," for the coefficients exactly represent the percentages from the analyses.

Assemble all expressions for silica and for bases, and equate according to the requirement.

	Silica.	Bases.
In ore	35	20
In limestone.....	$10x$	$50x$

Total silica $= 35 + 10x$ Total base $= 20 + 50x$

The requirement is:

$$SiO_2 : \text{Base} = 40 : 60$$

That is:

$$35 + x : 20 + 50x = 6 : 9$$

Whence, $x = 0.9286$.

$100x = 92.86$ = lb. of limestone required.

The "proof" consists in taking 100 lb. ore and 92.86 lb. limestone, and computing their actual weights of silica and base, thus:

Proof.

	SiO_2.	Base.
In 100 lb. ore.....	35.	20.
In 92.86 lb. "stone".....	9.286	46.43
	44.286	66.43

$$44.286 : 66.43 = 40 : 60$$

No one in practice would "bother" with second and third decimals of a pound, but for the sake of an absolute check, or proof, we carry value of x to fourth decimal, so that we get value of "$100x$" to second decimal, and final check comes within one-tenth of a pound.

Let us now do the above little problem by "excess."

(1) Ore. (Since silica is in excess, put base first in the proportion.)

$6 : 4 = 20 : 13.33 =$ silica required by its own base.

$35 - 13.33 = 21.67 =$ silica excess in the ore.

(2) Limestone:

$4 : 6 = 10 : 15 =$ base required by its own silica.

$50 - 15 = 35 =$ basic excess of the limestone.

(3) Base required by silica excess of the ore:

$4 : 6 = 21.67 : 32.505 =$ base required.

(4) Find weight of limestone required, by adjusting excess in ore to excess in limestone:

$$\frac{32.505 \times 100}{35} = 92.80$$

Proof. As the proof is identical it would be mere waste of space to repeat it.

This case is so elementary that it might be a matter of indifference whether to adopt the "excess" or the "equation." From this example, however, the two methods part company, i.e., it will be found that the equation method solves with fewer and fewer figures, relatively, as the complexity rises.

We now pass to the consideration of one ore and two fluxes, which involves also the two ratios, i.e., silica to bases and bases to one another.

(b)

	Ore.	Iron flux.	Limestone.
SiO_2	30	14	10
FeO	10	77	
CaO	..	..	50

This rises from four constituents to be figured, to six. We could insert a case with five constituents, but the illustrations are ample as it is.

The requirement as to composition of the slag is:

SiO_2	40 per cent
FeO	4 " "
CaO	20 " "
	100 " "

The use of two additional materials requires the use of two equations.

Call weight (i.e., lb.) of the iron-ore flux required $100x$

Call weight (i.e., lb.) of the limestone required $100y$

Now "assemble" the constituents.

Total silica $= 30 + 14x + 10y$

Total FeO $= 10 + 77x$

Total CaO $= 50y$

$(SiO_2 = FeO)$ $30 + 14x + 10y = 10 + 77x$ (1)

$(2 \times CaO = FeO)$ $100y = 10 + 77x$ (2)

Multiply (1) by 10 we get $553x = 210$.

$x = 0.3797$ $y = 0.3924$;

$100x = 37.97$ $100y = 39.24$

Iron-ore flux required $= 37.97$ lb.

limestone required $= 39.24$ lb.

Proof.

	SiO_2	FeO	CaO
In ore	30	10	..
In iron flux	5.32	29.4	...
In limestone	3.92	.....	19.62
	39.24	39.24	19.62

These numbers are in the required ratio, 4 : 4 : 2.

As the number of constituents to be taken into the account rises, the number of terms in the equations must also increase, but the number of unknown quantities remains two.

Problems involving four distinct substances in the slag, i.e., not merely as a physical fact, but as matters for separate adjustment, are not only very difficult to compute, but, what is more to the purpose, are usually impossible. That is, the materials will not lend themselves to the requirement. The method under discussion can be extended to these cases by the use of another unknown and the solution of three simultaneous equations. Usually it will result in a "minus" value, the accepted indication that we are trying to reconcile incompatible conditions. These cases are hardly worth consideration in detail. We pass now to the case of two basic groups in the ore.

(c)

	Ore.	Iron flux.	Limestone.
Silica	30	10	5
FeO	10	80	..
CaO	10	..	53

Requirement, same as in (b), viz: $SiO_2 = 40$; $FeO = 40$; $CaO = 20$.

Total silica $= 30 + 10x + 5y$

Total FeO $= 10 + 80x$

Total CaO $= 10 + 53y$

$(FeO = 2 \times CaO)$ $10 + 80x = 2 \times (10 + 53y)$ (1)

$(SiO_2 = FeO)$ $30 + 10x + 5y = 10 + 80x$ (2)

These are most readily solved by multiplying (1) by 7 and (2) by 8.

(1) $80x = 10 + 106y$

(2) $70 + 20 + 5y$ the reduced forms, become:

$500x = 70 + 742y$

$500x = 100 - 40y$

$x = 0.2040$. $100x = 20.40$ = required iron flux

$y = 0.1282$. $100y = 12.82$ = required limestone.

Proof.

	Silica	FeO	CaO
In ore	30.00	10.00	10.00
In iron flux	2.040	23.50	.....
In limestone	0.641	.....	6.795
	33.59	33.59	16.795
	40	40	20

It is seen that the statement and solution are about as quick with the additional base introduced as in (c). The only difference is in the adding in of an additional term involving the unknown, the solution is no more troublesome.

(d) We now introduce two bases into the "iron flux," leaving two in the ore, as in (c).

	Ore	Iron flux	Limestone
Silica	40	10	7
FeO	20	75	..
CaO	10	6	52

Let the requirement now be $SiO_2 = FeO = CaO$, i.e., each 33⅓ per cent.

Assemble the expressions for constituents as before: there are more terms, but no complications.

$$SiO_2 = 40 + 10x + 7y$$
$$FeO = 20 + 75x$$
$$CaO = 10 + 6x + 52y$$
$$(SiO_2 = FeO)\quad 40 + 10x + 7y = 20 + 75x$$
$$(FeO = CaO)\quad 20 + 75x = 10 + 6x + 52y$$

$x = 0.3831$. $100x = 38.31$ = required pounds of iron flux.

$y = 0.7004$. $100y = 70.04$ = required pounds of limestone.

Proof.

	SiO_2	FeO	CaO
In ore	40.00	20.00	10.00
In "flux"	3.83	28.73	2.30
In limestone	4.90	.....	36.42
	48.73	48.73	48.72

Weights all equal, as required by the condition.

Completed Form of the Problem

(e) We finally make the supposition that the limestone will carry a base of the iron group. This may be a very improbable case, but we have already indicated that these are examples in method, not attempts at physical probabilities. We now have the "complete" problem, that is, each and every one of the materials to be smelted contains silica and two basic groups.

Let us here ask the student or reader to try this problem by "excess." It becomes more like a Chinese puzzle than a problem in arithmetic. The first trials will result in a readjustment, approximating somewhat the desired weights, then, proof being applied, a revision and another approximation. This may be continued until the worker is satisfied that any closer result would be beyond reasonable demands of practice.

	Ore	Iron flux	Limestone
SiO_2	40	10	4
FeO	20	72	6
CaO	10	10	50

Requirement. $SiO_2 = 40$; $FeO = CaO = 20$ per cent.

As in all the problems, let $100x$ = pounds iron flux, $100y$ = pounds limestone.

$$SiO_2 = 40 + 10x + 4y$$
$$FeO = 20 + 72x + 6y$$
$$CaO = 10 + 10x + 50y$$
$$(SiO_2 = FeO)\quad 40 + 10x + 4y = 20 + 72x + 6y$$
$$(SiO_2 = 2 \times CaO)\quad 40 + 10x + 4y = 2 \times (10 + 10x + 50y)$$

We omit all operations and state values at once:

$x = 0.3169$. $100x = 31.69$ = weight in lb. of required "iron flux"

$y = 0.1753$. $100y = 17.53$ = weight in lb. of required limestone.

Proof.

	SiO_2	FeO	CaO
In ore	40.00	20.00	10.00
In "flux"	3.17	22.82	3.17
In "stone"	0.70	1.05	8.765
	43.87	43.87	21.935

These numbers are exactly as 40 : 40 : 20, as required.

The above examples may serve as our "types" for illustration of the method.

The use of "$100x$," etc., is recommended for the avoidance of fractional coefficients. The analyses given should always be revised and the percentages raised or lowered to the nearest unit. This for all purposes of slag calculation is amply close. For example, suppose an ore shows, as to slagging constituents:

SiO_2	39.8
FeO	17.3
CaO	9.7

We should not hesitate to use 40, 17 and 10 as coefficients, knowing how trivial would be the difference in the outcome.

Cases may occur in which the material does not admit the formation of the slag called for.

Example.

	Ore	Flux	Limestone
SiO_2	20	10	4
FeO	40	80	..
CaO	10	..	54

Required.—Slag of SiO_2, 40; FeO, 40, and CaO, 20 per cent.

$$20 + 10x + 4y = 40 + 80x$$
$$40 + 80x = 20 + 108y.$$

Upon attempting to solve these equations it will be found that either x or y gives a minus value, and, in fact, in any problem of this type a minus result indicates incompatibility of the material with the requirements. The above data are crude enough, and it would hardly require the "setting up" to show its impossibility, but cases might easily arise in which this would not be so readily perceived.

In "setting up" problems on this method it is not necessary to go through all the detail we indicated in solving the above ("a" to "e").

For example, the original analysis may (as simplified by putting units instead of fractions) be written with the unknown quantities annexed to the percentage figures at once, it being always understood that, when two fluxes are used, the weight of the first is to be $100x$ and of the second $100y$.

Example.

	Ore	Flux	Stone
SiO	35	$8x$	$6y$
FeO	8	$75x$	...
CaO	5	$3x$	$53y$

Now the "coefficients" are taken directly from the table of analyses. We have limited our statements in these problems strictly to the "analytical" form for slag requirement. The method itself, however, is subject to no such limitation, as we shall presently show.

It is frequently possible, when a chemical formula is desired, especially (as will usually be the case) if it be simple in structure, to pass directly from the formulistic statement to the equation, not only without the intervention of a calculated analysis, but with simpler coefficients. This point, with a few others relating to certain special cases, will be developed in our closing article.

The Colorado Scientific Society recently held two meetings at Telluride and Ouray, Colorado, at which practical talks were given to the mining men of those districts. Mr. Frank E. Shepard spoke at Telluride on the subject of modern mill design. At Ouray Mr. W. P. J. Dinsmoor discussed roak drills and air compressors.

Meeting of Institute of Metals.

The Institute of Metals.

The annual general meeting was held on the 16th and 17th of January, in London. The second day was devoted to the reading and discussion of several very interesting papers.

Corrosion.

Mr. Arnold Philip (Admiralty Chemist) read a paper entitled "A Contribution to the History of Corrosion: the Corrosion of Condenser Tubes by Contact with Electronegative Substances," this constituting the first of a series of contributions to the history of corrosion that Mr. Philip has promised to present to the Institute of Metals.

Mr. Philip's paper was devoted to an examination of the relatively small number of cases experienced by the Royal Navy in which localized corrosion occurred in condenser tubes made of Admiralty composition, namely, copper 70, tin 1, and zinc 29 per cent. The author made the interesting statement—interesting because the causes of corrosion have generally been regarded as so mysterious—that the causes of fully 90 per cent of the cases of corrosion observed in the establishments of the Royal Navy had long been known. In the author's opinion the main problems which remain to be solved concerning localized corrosion are, firstly, the explanation of the causes of rather less than 10 per cent of the cases which are now observed; and, secondly, the devising of a general means of preventing these and all other cases of corrosion superior to the method of protector bars, etc., of zinc, aluminium, steel, or iron, as at present employed.

Mr. Philip included in his paper a schedule of queries as issued by the Admiralty to those of its officials who are likely to be able to throw any light on the subject of the corrosion of condenser tubes. This list of questions is very similar to the Corrosion Enquiry Form recently issued by the Institute of Metals, and if all who are experiencing trouble with their condenser tubes would fill up the latter form (which is modeled to some extent on that of Mr. Philip's, and can be obtained from the Institute of Metals, Caxton House, Westminster, S. W.) there is little doubt that Mr. Philip's "10 per cent" of mysterious cases of corrosion would be mysteries no longer.

Mr. Philip's paper concluded with a consideration in detail of five very definite cases of corrosion of tubes used in the condensers of battleships, torpedo boats and electric generating plants of the Royal Navy.

Mr. G. D. Bengough, who opened the discussion, said Mr. Philip's experience led to four or five definite conclusions. He considered that the electrolytic theory sufficiently accounted for nearly all cases of corrosion which had come under his own observation. This point was very important, because that theory did not meet with approval in some quarters. Next, with Admiralty brass there were very few cases calling for other explanation than the ordinary causes of corrosion. Possibly a cheaper metal could be produced capable of resisting corrosion to the same extent as Admiralty brass.

Engineer-Rear-Admiral J. T. Corner said the paper showed clearly that the Admiralty brass tubes, when adequately protected, resisted corrosion; and if it occurred the blame would be on the users.

Mr. T. Vaughan Hughes remarked that in Admiralty tubes the corrosion in all cases seemed to be on the lower side in which the sea water was concentrated on emptying the condenser. The electrolytic theory appeared to offer considerable explanation of the effects of coal and ash dust. Information as to the exact shape of the corroded areas would be useful. Ten years' use would be required to produce the changes in the constituents of naval brass which Professor Carpenter, in his experiments on inversion in copper-zinc alloys, had effected in three months. There was a possibility of hitherto unsuspected changes occurring in the constitution of alloys.

Mr. A. E. Seaton mentioned that in the navy no defective tubes were encountered while their composition included a small quantity of tin. He agreed with Mr. Philip on the effects of drainage. Where the iron of the condenser had been employed as a preventive the corrosion of the iron was much more severe than that of the brass.

Mr. Anderson considered that electrical methods would solve the problem of prevention of corrosion; and he was experimenting in that direction. A large proportion of some sixty or seventy cases of which he had had experience during the last three months had been in power stations and the mercantile marine; but an appreciable number of these tubes were of Admiralty brass. The effect of an efficient protective mass could only be got when there was good electrical contact between it and the tubes. He had recently been observing the action of protective masses of special material and found that the current generated per block varied from 0.5 amp. to 1.25 amp.; while the average current in the condenser was about 1 amp. per thousand square feet of surface.

Mr. E. Rhead thought there was a possibility of electrical disturbance arising from the liberated gas from the condenser water coming in contact with the metal. The pitting of propeller blades occurred at points of low pressure, just where liberation of gas from the sea water would occur.

Mr. Philip in his reply, said that 90 per cent of the cases he had experienced were explainable by the electrolytic theory. Another factor was the exposure of the bottoms of the tubes to the action of air and sea water when the condenser was not working. He fully recognized the great importance of the unexplained 10 per cent of cases.

Inversion in Copper-Zinc Alloys.

A paper by Professor H. C. H. Carpenter followed on "Further Experiments on the Critical Point 470 deg. C. in Copper-Zinc Alloys."

In this paper it is shown that the so-called beta constituent in copper-zinc alloys is to be regarded below 470 deg. C., as an extremely minute and uniform complex of alpha and gamma particles. Its structural stability is so remarkable that even after six weeks' annealing at 445 deg. C. no appreciable coalescence of these particles has been observed in an alloy of exactly the eutectoid composition.

When, however, a few crystallites either of alpha and gamma are initially present in an otherwise pure eutectoid alloy, then, on annealing at 445 deg. C., this stability is comparatively easily destroyed. These crystallites constitute nuclei for the deposition of alpha and gamma, as the case may be, from the mixture, and eventually in both cases the final result is the same, viz.: coarse alpha, and coarse gamma, which can be seen with the naked eye, which have characteristic colors, viz.: alpha pale gold, and gamma pale bluish-grey, and which have the same etching properties.

The peculiarly persistent structural stability of the pure eutectoid alloy can be explained by supposing that at the inversion temperature on cooling the resolution of beta into alpha plus gamma takes place throughout the entire alloy almost, if not quite, simultaneously. This constitutes a favorable condition for the production of the inversion products in an amorphous form, because the forces operative in crystal production do not have time to come into play.

This view is in harmony with certain peculiarities which the freshly prepared alloy exhibits both in polishing and etching, which disappear when it has passed into a visibly crystalline condition. Further, the structural stability of the eutectoid alloy has been so much diminished by the presence of 4 per cent of aluminium that after two days' annealing at 445 deg. C. it was found to have undergone the typical lamella inversion such as is shown by the iron, ironcarbide eutectoid-pearlite. These facts constitute overwhelming evidence that below 470 deg. C. the beta constituent in copper-zinc alloys consists of the two-phase system, alpha plus gamma.

Mr. O. F. Hudson, opening the discussion, said the paper was

a reply to the criticisms on the author's earlier communication on the subject; and the microphotographs with which it was illustrated seemed to fully prove his point.

Dr. A. G. Gwyer considered that Dr. Carpenter's hypothesis was supported by almost conclusive evidence. A year ago the eutectoid theory and the polymorphic theory were both possibilities; but the author had now proved the correctness of his views.

Dr. Rosenhain asked what evidence the author had to warrant his departure from the ascertained diagram of Shepherd.

Mr. G. D. Bengough had always been convinced that Dr. Carpenter's explanation was right. He noticed that the change from the alpha state to the beta plus gamma was very rapid; and only the segregation of alpha and gamma into definite crystalline structures was slow. If the action were rapid there should be an abrupt alteration in physical properties about 475 deg. C., and if the action were slow the change in mechanical properties would proceed correspondingly.

Mr. F. Johnson remarked that experiments by Webb on locomotive firebox stays of Muntz metal screwed into the copper plate resulted in difficulties at the temperature of the experiment with diffiusion of zinc into the copper plate.

Mr. A. E. Thoine had always regarded spontaneous splitting as arising from a condition of the amorphous phase, and the tendency of the metal to revert to its natural soft state. Information as to the length of time required to split up the alpha in 70 — 30 brass would be useful.

Professor A. K. Huntington commented on the absence of any mechanical tests in support of the author's views, and considered that other points required explanation.

Dr. Carpenter replied that the experiments were being continued for the investigation of points on the practical side; and he hoped to present his results next September.

Heating of Alloys in Vacuo.

A paper by Professor T. Turner, on "The Behavior of Certain Alloys when Heated in Vacuo," was then read and discussed.

It was observed, during the course of some experiments conducted a year ago, that on melting brass in vacuo the whole of the zinc volatilizes, leaving the copper. This separation is quantitative, if the heating is not too prolonged and the temperature not above 1200 deg. C.

The behavior of other copper-zinc alloys when similarly heated was, therefore, investigated. A sample of "poisoned" brass, i. e., brass containing iron, lead, tin, arsenic and other impurities, was heated in a porcelain tube in vacuo at 1200 deg C., and the residue examined. All the zinc, lead and arsenic, and a little of the tin, volatilized, leaving a residue of copper, iron and most of the tin.

Larger scale experiments are also described, in which 70-30 brass was melted in a crucible, transferred to a large and well-lagged desiccator, and the whole quickly exhausted. The residue in the crucible was cooled and analyzed, and the loss in zinc recorded. As a result of these experiments it is suggested that heating in vacuo might be advantageously applied for the refining of crude copper, brass scrap, etc.

"Hard" zinc may be refined by heating in vacuo to 500 deg. C., i.e., to a scarcely visible red heat. Hard zinc is the residue from galvanizing baths, and contains about 5 per cent of iron. At higher temperatures some iron is carried over with the zinc, but at about 500 deg. C. all the iron remains in the residue. As the temperature necessary is so low, and as there is no loss of zinc by oxidation, there is reason to believe such a process would be commercially successful.

Some preliminary experiments on the equilibrium between zinc vapor, copper and copper alloys are also described.

Zinc itself volatilizes easily at 375 deg. C. in vacuo. A 60-40 brass readily loses zinc at 520 deg. C. and a 70-30 brass at 550 deg. C. On heating zinc with copper in vacuo, the metals not being in contact, the copper rapidly turns yellow at 380 deg. C., while the zinc is still solid, enough zinc volatilizing to form a surface layer of brass. Zinc distils readily in glass vessels in vacuo, the vapor being colorless and transparent. The zinc condenses in globules, having the appearance of mercury.

Sir Gerard Muntz said it was remarkable that the zinc had entirely separated from the copper; and microscopic investigation might furnish useful data bearing on the mechanical strength of metals.

Mr. T. Vaughan Hughes said that the volatility of metals in a high vacuum came prominently under his notice in connection with work on early incandescent lamps. Even platinum would volatilize in a vacuum; and it was not possible to expose metals to such conditions, even at low temperatures, with out volatilization occurring. Zinc could easily be evaporated out of brass without using a vacuum; but it has been discovered that a certain combination of gases prevented that action to a very great extent, and he had been working on these lines.

Properties of Alloys at High Temperatures.

Mr. G. D. Bengough presented a paper on "A Study of the Properties of Alloys at High Temperatures."

A series of tensile tests on selected metals and alloys are described. The tests were carried out at temperatures varying from the ordinary temperature to the neighborhood of the melting points of the materials used. A special form of apparatus was used for the tests, and a full description of it is given in the paper.

A number of unexpected results have been obtained. The curves showing the variation of mechanical properties with temperature show certain "mechanical critical points" in the neighborhood of which the direction of the curves alter rapidly, and this phenomenon occurs even in the case of commercially pure metals such as copper and aluminium. A theoretical explanation of the shape of the curves is proposed and discussed.

The paper is illustrated by a large number of curves, tables, and photomicrographs.

Sir Gerard Muntz led the discussion and said that Mr. Bengough seemed to misapprehend the real nature of Muntz metal. It was accepted that anything containing less than 60 per cent copper was not Muntz metal. With class B Muntz metal the author's conclusions were identical with those arrived at by works experience as to the great difference in elongation and ductility as compared with true Muntz metal, which indicated the presence of too much zinc in the metal. His own experience induced a belief that rolled rod would have a longer life and give better results than extruded rod, although at first the latter might give equally good results on mechanical tests; but later a change took place in the crystalline structure and made the extruded rod less reliable. The paper helped to explain this change.

Professor T. Turner thought that the paper suggested a reason why the tensile strength of cast metal fell gradually as the temperature increased; and helped to elucidate problems connected with hardness caused by working. He was of opinion that the amorphous inter-crystalline structure originated in the action of the working between the crystalline areas. As a rule, it was impossible to increase the tensile strength of the material in the cast state to more than double.

The Influence of Oxygen on Arsenical Copper.

Mr. R. H. Greaves presented a paper on "The Influence of Oxygen on Copper Containing Arsenic or Antimony."

The experiments described were made to determine the influence of oxygen on certain mechanical and physical properties of copper containing either arsenic or antimony in quantities up to 0.5 per cent. A number of comparative tests in which the metals were cold-rolled down to 0.02 in., or drawn into fine wire, showed that with increasing arsenic the metal may take up more and more oxygen without suffering deterioration in its capacity for rolling. This quantity of oxygen increases from about 0.05 to 0.2 per cent as the arsenic in-

creases from 0 to 0.2 per cent., then more slowly to about 0.28 per cent, with 0.5 per cent arsenic. Above this point the malleability falls off, and with still more oxygen the metal becomes "cold-short." The action of oxygen on copper containing antimony is similar, but in this case a small quantity (about 0.1 per cent) effects a distinct improvement in the malleability of the metal. The ductility was similarily affected by oxygen. Tensile tests on the case metals showed that increase in oxygen from 0.15 to 0.4 per cent caused a rapid diminution in elongation; the effect on the maximum stress was not marked.

Oxygen has little effect on the hardness (measured by the Shore scleroscope) until a limit is passed, depending on the arsenic or antimony present; above this, the hardness increases rapidly. This limit is at about 0.3 per cent with 0.4 per cent arsenic, but is less in presence of antimony. The first addition of arsenic or antimony decreases the hardness of copper containing oxygen. Measurements of electrical resistance show that oxygen diminishes the conductivity of copper containing arsenic, but increases that of copper containing antimony; the quantitative effect of the oxygen has not yet been determined.

In an appendix, methods of determining oxygen in copper are discussed. Without denying the accuracy of other standard processes, the author suggests that oxygen may conveniently, and with a high degree of accuracy, be determined by reducing in hydrogen, and weighing the water formed.

In the discussion Sir Gerard Muntz said that unless the proportion of oxygen were taken into account, consideration of the effect of arsenic would be useless. His own experience was confirmed by the author's experimental results; but he expected Mr. Greaves' figures for oxygen would be with the decimal point moved one place to the left. When arsenic was 0.5 he should expect the oxygen to be 0.02 to 0.015. With higher oxygen there was a tendency to increase of tensile strength, and rapid reduction of elongation; while with less than 0.015 per cent of oxygen a very ductile soft metal of little practical value was obtained.

Mr. L. Archbutt said he did not consider that any increase of accuracy resulted from the author's method of weighing the water, and it certainly involved much more work and trouble. If railway companies specified the amount of oxygen, there would be great difficulty in working to such a specification. If the arsenic content were specified the oxygen was left to the manufacturer, and when mechanical tests were fully specified other tests were not specified.

Mr. F. Johnson thought that the author had exercised a wise choice in taking arsenic and antimony for experiment. The results agreed with his own previous conclusions that both for hot and cold rolling oxygen greatly improved copper containing antimony. It had been found possible to draw into wire a copper containing more than 3 per cent of antimony and 0.04 per cent of oxygen. Tensile tests of cast copper were unsatisfactory; the wrought material yielded more reliable results. The author stated that oxygen in arsenical copper lowered the conductivity but raised it in antimonial copper. That appeared to confirm the contention that in arsenic-oxygen-copper alloys the oxygen occurred in free CuO_2 and the arsenic was in solid solution.

In the antimonial alloy part of the antimony united with the oxygen instead of going into solid solution.

Nomenclature of Alloys.

Dr. W. Rosenhain presented a "note on the nomenclature of alloys."

In this paper Dr. Rosenhain raises the question of the nomenclature of non-ferrous alloys and puts forward some tentative suggestions to serve as a basis for discussion. He draws attention to the confusion in nomenclature which exists at the present time, particularly as regards such terms as "brass" and "bronze" which are frequently applied in contradictory ways. A system of nomenclature is put forward for consideration in which alloys are classified according to the system of binary alloys to which they approximate most closely and class names for such binary systems are advocated—such as the term "brass" for alloys consisting principally of copper and zinc; "bronze" for alloys consisting principally of copper and tin; and so on. The additional metals present in any particular alloy would be indicated by additions to the class name, so that an alloy consisting of copper and zinc with a comparatively small percentage of manganese would be called a "manganese brass." Some of the difficulties which have to be overcome by such a system are pointed out, and the suggestion is made that the whole subject should be dealt with by a representative committee of members of the Institute who should be asked to draw up a system of nomenclature for use in scientific and industrial work, particularly in specifications. Dr. Rosenhain adds that he does not wish to interfere with ordinary trade names used in connection with the advertisement and sale of alloys of special properties, particularly when these are non-descriptive, but generic names such as "brass" and "bronze" should be used accurately, and a satisfactory and widely recognized system of nomenclature is none the less desirable.

Tin and Lead in Brass.

Mr. F. Johnson presented a paper on "The Effect of Tin and Lead on the Microstructure of Brass."

In this paper the author recorded the results of experiments made with the object of ascertaining the structural relations which exist between lead and tin when present in brass where the ratio of copper to zinc is 2 : 1.

He found that, by itself, tin was thrown out of solution in the alpha phase (70 copper, 30 zinc) in the form of a hard pale-blue compound (probably $SnCu_4$) some time after solidification of a slowly-cooled alloy. Annealing, either preceded by rolling or not enabled this compound to again pass into solution in the alpha phase.

In a brass consisting of the alpha and beta phases, where the latter was present in sufficient amount (e.g., naval brass and Muntz metal) the copper-tin compound was much more soluble, being apparently retained by the residual beta.

In an alloy where the beta phase exists in an unstable form (such as the alloy containing 2 parts copper to 1 part zinc) it is insufficient in amount to retain the tin compound which is deposited mainly as a thin envelope or film separating the beta from the alpha phase, thus giving a reticulated appearance to a polished and etched section.

With regard to lead, the author found that this acted independently of the tin exhibiting behavior similar to that of lead in ordinary brass or in copper. That is to say it retained its individuality and existed in small particles unalloyed with more than mere traces of any other metal, these particles tending to segregate toward the areas last to solidify. In the presence of excess of the beta phase lead is probably held in solution therein.

As a result of the observation the author strongly advocates a very thorough annealing of all cast material of the 70-29-1 and 62-37-1 compositions (Admiralty and naval brass respectively) before subjecting it to rolling or drawing, in order that the brittle tin compound may be enabled to pass into solution.

Malaysian Tin Exports.—The following table (from the Federated Malay States Government *Gazette*) shows the weight of tin (tin exported in the form of ore having been taken at 70 per cent of the gross weight of the ore) exported from the Federated Malay States during 1910 and 1911 (picul = 133 1/3 pounds):

States	1910 Tin	1910 Tin contained in tin ore	1910 Total	1911 Tin	1911 Tin contained in tin ore	1911 Total
	Piculs	*Piculs*	*Piculs.*	*Piculs*	*Piculs*	*Piculs.*
Perak	109,867	311,468	421,335	97,835	339,504	437,339

The Nathusius Electric Steel Furnace.

By Prof. W. Lipin.

Among the electric arc furnaces for steel refining the Heroult furnace has so far found most extended use in practice. There are, however, in operation also quite a number of other types of electric arc furnaces for steel refining, like those of Girod, Stassano, and Keller.

More recently a new electric steel furnace has been designed by Nathusius. In practical use in the steel works at Friedenshütte, Upper Silesia, Germany, it has proven very satisfactory and economical. This furnace will be described in the following article. The patents for this furnace are owned by the Westdeutsche Thomasphosphat Werke, G.m.b.H., Berlin, W. 35

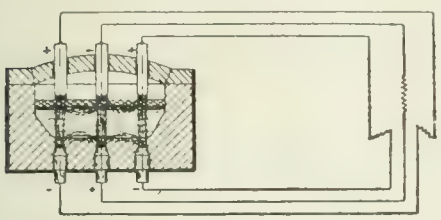

FIG. 1.—PRINCIPLE OF NATHUSIUS FURNACE.

The first experiments with a Nathusius furnace of 1-ton capacity were made some years ago at the steel works in Friedenshütte and the results then obtained were so satisfactory that in June, 1909, a new furnace of 3 tons capacity was started in operation at that plant. This was soon afterward changed into one of 5½ tons capacity.

The Nathusius type is a combination of the Héroult type and Girod type, but embodies also a third novel feature, that is, the heating of the bottom by the current from the bottom electrodes. The Nathusius furnace is, therefore, a combined arc and resistance furnace.

Fig. 1 shows the principle of the furnace in its simpler form. The horizontal section through the hearth is circular. From the top are suspended three carbon electrodes, the lower terminals being near the slag layer, as in the Héroult furnace. Three steel electrodes are embedded in the bottom of the hearth. They do not pass, however, all the way through the bottom up to the metallic bath, but only to about the center of the height of the bottom, so that their upper end surfaces are covered with a layer of dolomite of 30 to 35 cm thickness.

The high-tension, three-phase currents which are generated either in a special three-phase generator or supplied from the general power plant of the steel works are fed to the high-tension circuit of a step-down transformer, from the low-tension side of which the electrical energy is supplied to the furnace.

There are three paths of the currents within the furnace: (1) From the top electrodes to the neutral point within the bath through arcs playing between the lower ends of the top electrodes and the bath; (2) from the bottom electrodes to the neutral point within the bath, and (3) from the top electrodes directly to the bottom electrodes. It is very probable that currents also pass directly from one electrode to another in the upper group of electrodes as well as in the lower one.

The arcs playing from the lower ends of the upper electrodes produce a very high temperature in the slag (just as in the Héroult furnace) and cause a very energetic reaction. The passage of the current in various directions causes a very thorough heating of the metallic bath and of the slag, as well as of the furnace bottom. Further, there is a rotation of the metallic bath around the axle of the furnace and a movement of the bath between the electrodes toward the center. These movements are probably due to the use of three-phase currents producing a rotary magnetic field. This is true for the top electrodes as well as for the bottom electrodes. This automatic circulation and mixing of the bath results in a uniform temperature so that the steel made in the furnace is very homogeneous.

The displacement of the neutral point from the transformer or generator into the furnace* also has the advantage that the arrangement acts like a buffer, in so far as sudden current rushes which may have such a deleterious effect on the generator, are greatly reduced in intensity.

These properties of the Nathusius furnace I consider to be important advantages over other arc furnace types.

At Friedenshütte the 6000-volt, three-phase currents of the supply network are transformed by a three-phase transformer down to 110 volts. For connection of the electrodes with the transformer flat copper bars are used, so dimensioned as to carry continuously a current of 2500 amp.

Fig. 2 is a wiring diagram, the figures of the volts and amperes being mean values. *A* represents ammeters, *V* voltmeters and *W* wattmeters. During the normal operation the voltages have the following normal values. Between any two top electrodes the tension is 110 volts, between the top electrodes and the bottom electrodes it is 63 volts, and the tension between any two bottom electrodes is 15 volts.

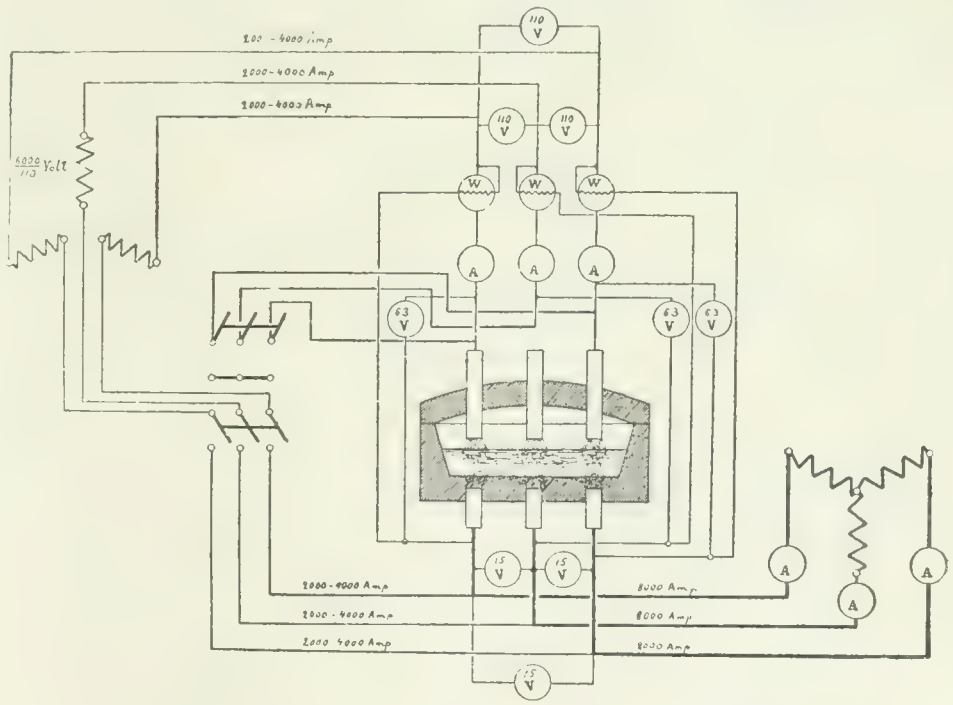

FIG. 2.—WIRING DIAGRAM OF NATHUSIUS FURNACE.

An additional transformer is also provided by means of which the energy supply to the bottom electrodes can be raised at will in order to heat the hearth and bath more strongly from the bottom. However, the absolute necessity of this additional transformer is doubtful. At present the furnace operates very satisfactorily without an additional transformer, since there

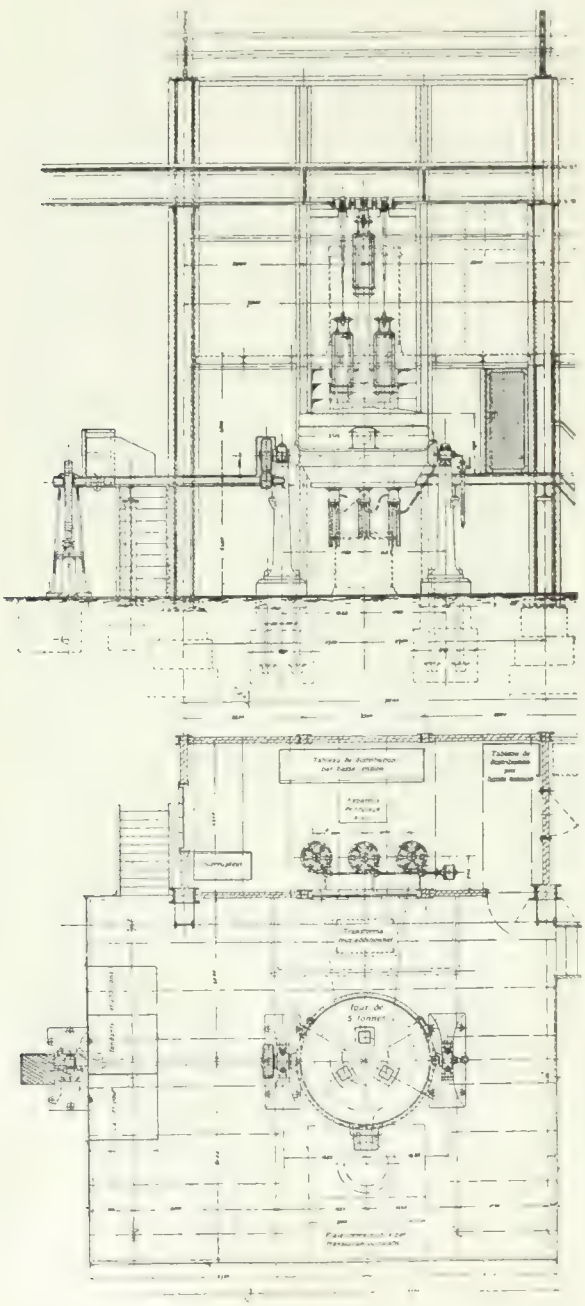
*This is shown in Fig 2, and further explained in the American patent of Nathusius (this journal, vol. IX., p. 608).—Editor.

is automatic regulation of the energy supply to the upper or lower electrodes. This problem is now being studied by the Bergmann Elektricitäts Werke, A. G., in Berlin, and will be solved shortly.

Furnace Construction.

The Nathusius furnace in operation in Friedenshütte is designed for a capacity of 5 to 6 tons (in the average 5½ tons). The horizontal cross-section is circular. There are three doors, arranged symmetrically (that is, spaced at angles of 120 deg. with respect to each other).

The door on the front side is provided with a launder for



charging molten metal from the basic converter and for discharging the finshed steel. Three carbon electrodes are suspended from the top through the arched roof.

The inside diameter of the hearth space is 2170 mm, the height of the center of the arched roof over the bottom of the hearth is 670 mm.

The upper carbon electrodes, which have a cross-section of 250 x 250 mm, are water-cooled. The lower electrodes are cast from steel (without any mechanical machining) and have a circular cross-section with a diameter of 250 mm. They are embedded in the bottom and are also water-cooled.

The whole furnace is enclosed in sheet iron, reinforced by a strong steel ring with two journals. The two journals which are used for tilting the furnace in order to discharge the steel rest in two bearings of a stator frame. Such a tilting arrangement is very convenient, but is suitable only for small furnaces. For larger furnaces with a capacity of more than 6 tons Nathusius uses a rack-and-pinion arrangement for tilting. Compressed air is used as the power for tilting at Friedenshütte.

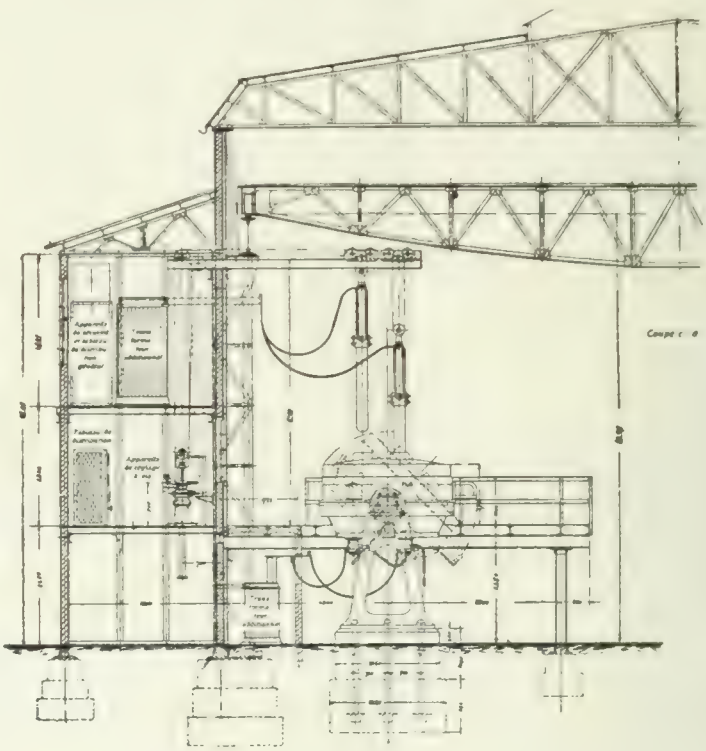


FIG. 3.—SECTIONS OF 5½-TON NATHUSIUS FURNACE.

The whole furnace frame, made of sheet iron, is closed. The roof can be easily removed as in the Héroult furnace.

The furnace roof is lined with dinas brick (silica brick) of the Lütgen or Stella (Willisch) brands. The thickness of the roof lining is 250 mm. The thickness of the bottom must not be less than 600 mm. The steel electrodes should extend upwards to about the center of the height of the bottom so that they are embedded in the lower half of the furnace bottom.

The position of the upper carbon electrodes can be regulated by means of cables running over rolls. Current is supplied to each of the upper electrodes through twelve flexible copper laminas and to each of the bottom electrodes through six cables from the main transformer and six cables from the additional transformer.

The upper electrodes are separately water-cooled, i.e., each water jacket has its individual pipes for the supply and exit of the cooling water. The bottom electrodes have a common cooling device, since their water jackets are connected together by pipes.

All measuring instruments are placed in a special room separated from the furnace by a glass wall. The regulation of the distance of the carbon electrodes from the bath is done by hand; the man attending to this has to watch constantly the readings of the voltmeters.

The design of the furnace in operation at Friedenshütte is given in three sections in Fig. 3.

The design of a 12-ton Nathusius furnace is shown in Fig. 4. For tilting a rack-and-pinion arrangement is used, the power being supplied by an electric motor. The three upper

electrodes have a diameter of 400 mm. Instead of three bottom electrodes there are provided six steel electrodes, connected in pairs. These ensure a better distribution of the energy in the bath, which is desirable for maintaining a uniform temperature in the bath, especially when the horizontal section is of large dimensions. Otherwise the equipment of the 12-ton furnace is the same as that of the 6-ton furnace.

Concerning the position of the neutral point in the Nathusius furnace and the energy consumed in heating the bottom from the bottom electrodes the Bergmann Elektricitäts Werke gives the following interesting notes:

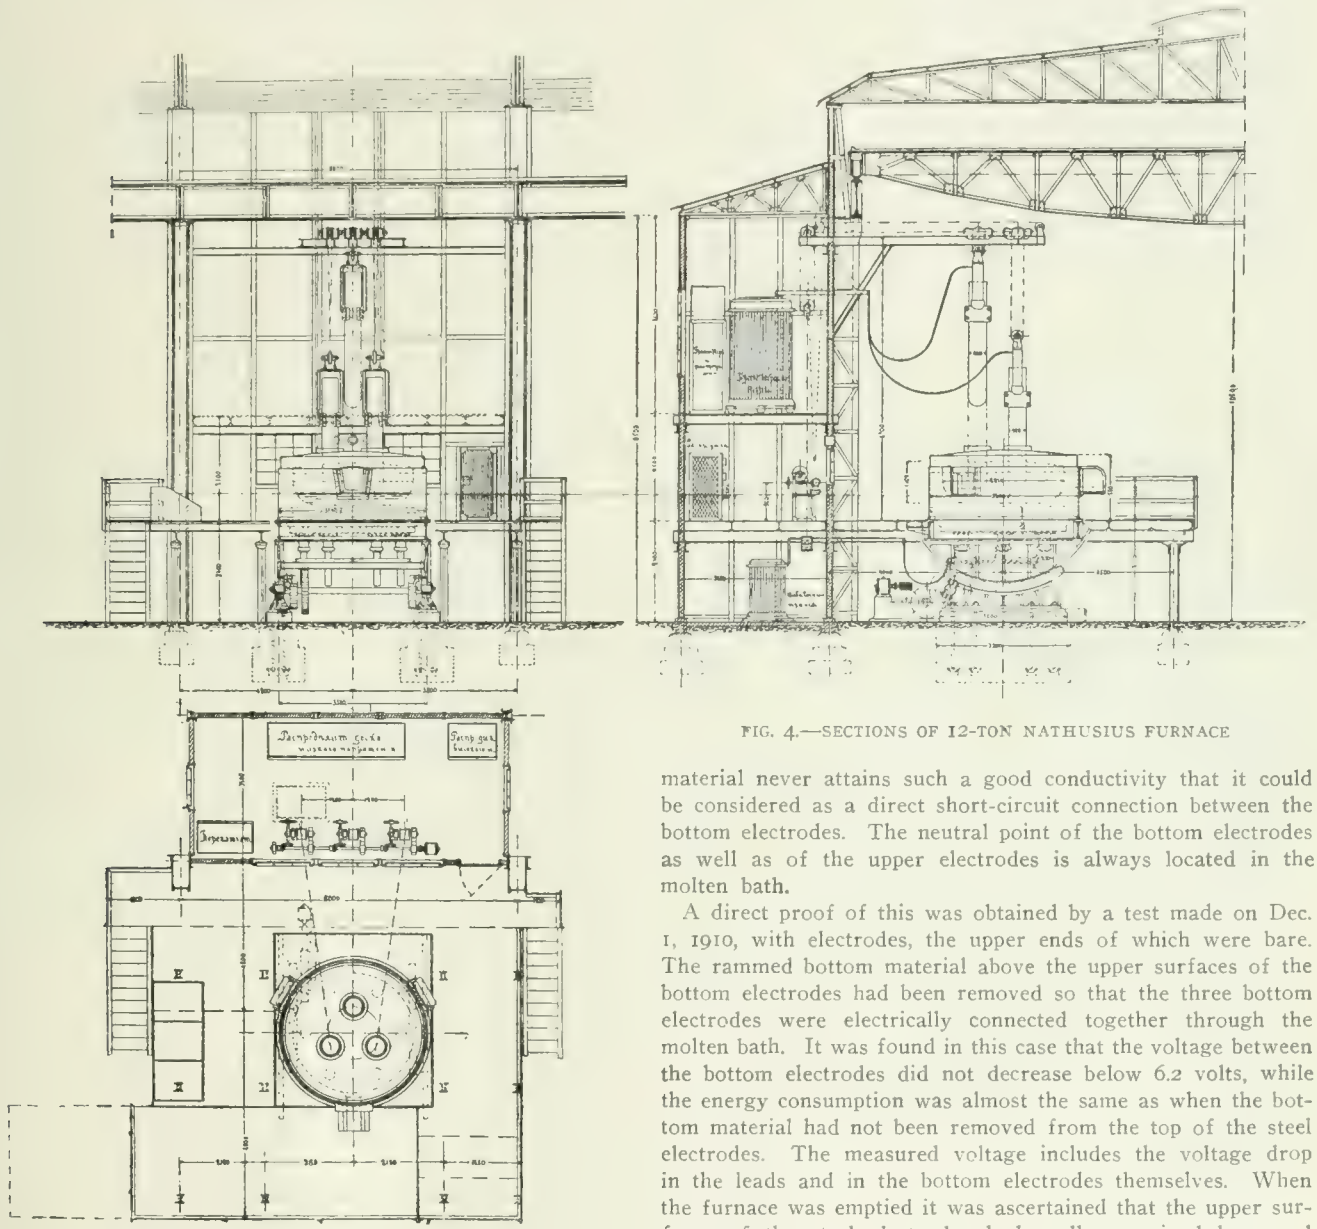

FIG. 4.—SECTIONS OF 12-TON NATHUSIUS FURNACE

The most characteristic feature of the Nathusius type of furnace is the possibility of distributing at will the heat effect between the upper and lower groups of electrodes. When a new furnace is to be designed, it may be specified that 50 per cent or more of the total heating effect is to be supplied through the bottom electrodes, and the design of the transformer and additional transformer can then be made accordingly. But even with the furnaces now in existence the heating from the bottom represents quite a considerable percentage of the total heating effect.

Repeated measurements have shown that with 12 volts between the bottom electrodes the power introduced through the bottom electrodes is 32 kw to 38 kw (while the heating effect of the upper elcctrodes is 110 kw to 150 kw). When the connections are changed to 24.3 volts the power introduced through the bottom electrodes rises to 90-95 kw (while the heating effect of the upper electrodes is 110 kw to 115 kw).

All measurements show that when a new run begins, that is, when the bottom is relatively cool, the power consumption of the bottom electrodes is less than at the end of a run, although the voltage between the bottom electrodes is a maximum at the beginning. This fact proves that the resistance of the molten bath and of the furnace bottom material decreases more rapidly than the voltage.

On the other hand, it is thereby also proven that the bottom material never attains such a good conductivity that it could be considered as a direct short-circuit connection between the bottom electrodes. The neutral point of the bottom electrodes as well as of the upper electrodes is always located in the molten bath.

A direct proof of this was obtained by a test made on Dec. 1, 1910, with electrodes, the upper ends of which were bare. The rammed bottom material above the upper surfaces of the bottom electrodes had been removed so that the three bottom electrodes were electrically connected together through the molten bath. It was found in this case that the voltage between the bottom electrodes did not decrease below 6.2 volts, while the energy consumption was almost the same as when the bottom material had not been removed from the top of the steel electrodes. The measured voltage includes the voltage drop in the leads and in the bottom electrodes themselves. When the furnace was emptied it was ascertained that the upper surfaces of the steel electrodes had really remained bare and had not been covered with any bottom material.

In any case this proves that the neutral point is in the bath and the heating effect of the bottom electrodes represents quite a considerable percentage of the total heating effect.

Operation.

The lining of the bottom consists of ordinary dolomite*, as in the open-hearth. After the furnace has been preheated by a wood or coke fire, a small current is turned on, whereby the bottom is well heated. After the furnace has been properly heated up, the charge is made up.

*In the American patent of Nathusius (this journal, vol. IX., p. 608) the lining is said to consist of ordinary burned dolomite with tar as binding agent.—Editor

First 75 kg to 80 kg of iron ore (Kriwoi Rog) and 40 kg to 50 kg of lime are fed into the furnace, whereupon molten metal is charged either from the basic converter or open-hearth as the case may be. After a few minutes the upper electrodes are lowered and the current is switched on.

The electrodes must be lowered gradually, because the pouring of the molten metal on the ore causes a rather energetic reaction and the boiling or spatting of the charge is liable to damage the electrodes.

After the current has been switched on and the boiling has stopped, 50 kg to 70 kg of ore and 70 kg to 80 kg of lime are added to the furnace charge. After about an hour the first sample is taken and if the metal is found to have become sufficiently soft, i.e., if the greatest part of manganese, carbon, and phosphorus has been removed, the furnace is tilted and a part of the slag is run off.

The process is continued in the same way until the samples show the metal to be quite soft; a few shovels of lime are then charged in order to make the slag thicker, the current is cut off, the electrodes are raised, and after the furnace has been tilted somewhat, the slag is carefully removed. The furnace is then tilted back, the electrodes are lowered and the current is turned on again.

To produce a desulphurized slag a mixture of 15 kg of fluorspar, 15 kg of sand, and 40 kg of lime are added. After about 10 minutes a certain quantity of 75 per cent ferrosilicon is added for deoxidation of the metal. The whole desulphurizing process lasts 35 to 40 minutes and during this period the temperature of the furnace is raised as much as possible. The temperature in the bath is tested during this period with the aid of a thin iron rod. When the furnace is sufficiently hot, ferromanganese and special alloys are added and the steel is then poured from the furnace into the ladle. Aluminium is added in the ladle.

With respect to current and voltage, the current per phase during the first period of the process is from 3500 amp to 4000 amp and the power about 200 kw. If the furnace has cooled off somewhat before a new run, the bottom is reheated by means of the auxiliary transformer, the current per phase being 6000 amp to 8000 amp, which for a tension of 15 volts to 20 volts between the bottom electrodes corresponds to 120 kw to 160 kw. At the end of the first period (when the sample is taken), the secondary current of the main transformer is reduced to 2000 amp per phase.

The length of the whole run is from 2½ to 3½ hours. But, as will be seen later on, this is extraordinarily long, on account of the unsuitable location of the plant: the furnace itself, which operates in excellent shape, is not to be blamed on this account.

The energy consumption varies between 270 kw-hours and 290 kw-hours per ton for runs in which ordinary or special steels (for springs, tools, etc.) are made and increases to 400 kw-hours in the production of very soft steel.

Data on a few runs follow.

Run 616. (Special steel.)

10:25 a. m.—Ore and lime are charged and the molten metal is run into the furnace.
10:40—Removal of part of the slag.
12—Removal of slag.
12:10—Addition of desulphurizing slag.
12:55—Final sample taken. Addition of deoxidants.
1:10—Discharge of finished steel.

The run, therefore, lasted 2 hours and 45 minutes.

In this case the molten converter steel was charged into the electric furnace after it had cooled off somewhat because it had been empty for 50 minutes.

Five thousand and six hundred kg of ingots were obtained; the energy consumption was 1620 kw-hours, or 290 kw-hours per ton of steel.

Run 617. (Special steel.)

2:10 p. m.—Charge of ore and lime. Charge of molten metal.
3:35—Removal of part of slag.
4:10—Removal of slag.
4:20—Preparation of desulphurizing slag.
5:00—Discharge of finished steel.

The run, therefore, lasted 2 hours and 50 minutes. When the furnace was charged it had been empty for an hour.

Five thousand three hundred and [illegible] kg of ingots were obtained. The energy consumption was [illegible] kw-hours, or 270 kw-hours per ton of steel.

Run 622. (Special steel.)

11:40—Charge of ore, lime and molten converter metal.
1:45—Removal of part of slag.
2:00—Removal of slag.
2:12—Preparation of desulphurizing slag.
2:50—Addition of ferromanganese and discharge of finished steel.

The run lasted, therefore, 3 hours and 10 minutes. The furnace had been empty for 1 hour and 5 minutes when it was charged.

The specific energy consumption was 290 kw-hours per ton.

In runs making special steels the composition of materials is as follows:

Kriwoi rog ore, 120 kg to 140 kg; lime, 100 kg; fluorspar 15 kg; sand, 15 kg; ferromanganese, 36 kg.

Run making soft steel.

12:15—Charge of ore and lime and molten metal.
2:15—Removal of part of slag.
3:30—Removal of slag.
5:10—Addition of deoxidants.
5:10—Discharge of finished steel.

The run lasted, therefore, 4 hours and 55 minutes. The energy consumption was 2400 kw-hours; 6000 kg of ingots were produced. The specific energy consumption was, therefore, 400 kw-hours per ton of steel.

The consumption of materials was as follows:

Manganese ore, 100 kg; lime, 105 kg; fluorspar, 12 kg; sand, 12 kg; ferromanganese, 25 kg; petroleum coke, 18 kg.

In order to show the results of the refining process, I give some analysis of the original converter metal and the finished electric steel obtained in those runs during which I was present in Table I.

TABLE I.

Number of run	Converter Metal C	Mn	P	S	Electric Steel C	Mn	P	S
616	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
617	0.063	0.27	0.045	0.02	0.057	0.12	0.003	0.015
622	0.066	0.49	0.065	0.04	0.050	0.11	0.002	0.015

Besides these three runs, which I followed very carefully, I give some analyses from the works records in Table II.

TABLE II.

Converter Metal C	Mn	P	S	Electric Steel C	Mn	P	S
0.06	0.45	0.06	0.04	0.058	0.12	0.002	0.008
0.06	0.35	0.03	0.028	0.065	0.12	0.002	0.009
0.06	0.40	0.05	0.02	0.056	0.085	0.003	0.008
0.07	0.43	0.06	0.03	0.064	0.14	0.018	0.009
0.056	0.41	0.028	0.03	0.060	0.19	0.004	0.008
0.053	0.37	0.04	0.035	0.060	0.12	0.007	0.008

For soft charges the results of the electric process are also excellent, as will be seen from Table III.

TABLE III.

Converter Metal C	Si	Mn	P	S	Electric Steel C	Si	Mn	P	S
0.056	?	0.52	0.04	0.02	0.06	0.01	0.375	0.002	0.008
0.06	?	0.38	0.035	0.03	0.11	0.15	0.55	0.003	0.008

The analyses show that the removal of phosphorus and sulphur is accomplished successfully and that the steel obtained is distinguished by its purity.

Of course, the quality of electric steel depends not only on the chemical purity of the metal, but also on the freedom from all blow-holes, etc. It is to be said that in this respect the

electric steel produced in the Nathusius furnace is absolutely perfect and is dense and homogeneous even at the ends of the ingots.

Chemistry of Refining Process.

In now discussing the chemistry of the refining process it should first be pointed out that in Friedenshütte the time of the refining process is lengthened by delays in the charging of the converter metal and also by the fact that the electric furnace is charged with finished converter steel, which is ready for casting, containing 0.4 to 0.5 per cent manganese. In the electric furnace the whole refining process is lengthened by the time required for the removal of the manganese and the process would undoubtedly work much more rapidly and much more economically if the furnace was charged with metal from a basic converter before spiegeliron or ferromanganese is added to it.

The removal of the sulphur in the electric furnace is as complete as in the Heroult furnace, as will be seen from the analyses.

Dr. Geilenkirchen and Professor Eichhoff contribute the successful removal of sulphur in the Heroult furnace to the formation of calcium carbide, due to the action of the arc on the lime slag, when it contains no longer any metallic oxides, that is, iron and manganese oxides. During the desulphurizing period of the run they believe that the petroleum coke deoxidizes the lime and converts it into carbide according to the equation

$$CaO+3C=CaC_2+CO.$$

The calcium carbide then reacts with the FeS and yields calcium sulphide, which passes into the slag.

This explanation must be considered as rather artificial since with the greatest care exercised during the deoxidation process while the slag is entirely white, it contains nevertheless a small amount of metallic oxides. In this case the petroleum coke will deoxide without doubt iron and manganese oxides, but not lime.

It is far more probable that the removal of the sulphur gas is accomplished by the well-known reactions which occur in a blast furnace as well as in an open-hearth furnace, as follows:

$$2CaO+2(Fe \text{ or } Mn)\ S+C_2=2CaS+2(Fe \text{ or } Mn)+2CO$$

$$2CaO+2(Fe \text{ or } Mn)\ S+Si=A\ CaS+2(Fe \text{ or } Mn)+SiO_2$$

In a Heroult furnace the removal of the sulphur takes place far more rapidly than in an induction furnace. This is easily explained without any artificial theory concerning the formation of calcium carbide in the furnace.

In the Heroult furnace the arc cuts through the layer of slag and the current passes through the metal along contact surface with the slag. An enormous amount of heat is produced in the slag and this causes an energetic reaction with the formation of calcium sulphide. This does not take place in the induction furnace because the slag is heated to a much smaller degree.

As to the Nathusius furnace and the removal of sulphur in the same, it must be said that the high temperature produced by the three arcs in the slag causes as complete a desulphurization as in the Heroult furnace, even without the addition of petroleum coke and without any suposition of the formation of calcium carbide.

I am of the opinion that in all furnaces in which an arc enters the slag and in which the slag is heated by the passage of the current along the surface of contact between metal and slag, all reactions must be much more successful and much more energetic than in furnaces in which the bath is heated in a different way. In this respect the Nathusius furnace is quite perfect. Besides the arcs which pass through the slag and the further passage of the current along the contact surface of metal and slag (as in the Heroult furnace) there is also a passage of current from the upper electrodes through slag and metal and heating them (as in the Girod furnace). Moreover, part of the energy is supplied from the bottom electrodes through the upper layer of the bottom into the bath, heating the lower layer of the bath and especially the bottom hearth. Therefore, the whole metallic bath, the slag layer, and the bottom material are all heated at the same time.

This is a very important advantage of the Nathusius furnace over other systems.

Further, with this system it is possible to connect the furnace directly to the central station without having to fear any sudden fluctuations of load which would damage the generators, since the slag layer, the steel bath, and the bottom material act like an electric buffer and counteract the load fluctuation due to short circuits of the arcs. For this reason the furnace does not need any regulation at normal running.

Finally, an additional transformer suitably chosen enables one to vary at will the energy supply to the bottom electrodes and to heat the metallic bath and the bottom to a higher temperature when required.

Reliability of the Furnace.

At first sight the bottom of the hearth, especially the mass rammed on the upper surfaces of the bottom electrode, seems to represent a weak point of the Nathusius furnace. It might be feared that cracks might form and the bottom would be damaged more rapidly than the other parts of the lining. However, practice shows that these fears are unfounded.

The bottom requires not more attention and care than that of an ordinary basic open-hearth furnace.

While I was present at Friedenshütte it became necessary to stop operation in order to change the roof, which was burned through at one place; the furnace was not used from Friday to Monday. The roof was taken off and, after the furnace had cooled down, the hearth bottom was cleaned from slag. The bottom lining was in very satisfactory condition, although it had stood 445 furnace charges without any great repairs. This figure is taken from the works records. The condition of the hearth bottom would have permitted continuation of operation for quite a time and it was not yet possible to say when repairs would have become necessary.

The arched roof had burned through at one place while I was at the works and was repaired by putting on a brick plaster. But as there was no rush of work and as considerable heat was lost through this defective part of the roof, the operation of the furnace was stopped to change the roof. The roof which was then removed had stood eighty-six or eighty-seven charges. In general, the life of a roof is ninety to ninety-five charges, according to the works records.

The weakest point of electric steel furnaces is to be found in the carbon electrodes. The wear and tear of the carbon electrodes is quite considerable with the Nathusius furnace in Friedenshütte as well as with the Heroult furnace in Remscheid and at the Obuchow works. For the Nathusius furnace in Friedenshütte, however, the electrode consumption is somewhat reduced by the use of three-phase currents and the smaller cross-sections employed on that account. In the manufacture of carbon electrodes no brilliant success has yet been obtained.

First Cost.

The following figures on *first cost* relate to conditions in Germany.

A furnace of 2 or 3 tons capacity cost[illegible]0.

A furnace of 5 or 6 tons capacity costs $6,750.

A furnace of 8 tons capacity costs $8,500.

A furnace of 12 tons capacity costs $10,000.

These figures do not include the cost of the generator, transformer, cables, etc., nor the license fee.

Now it must be admitted that a refining cost of $4.20 per ton is much too high. The reason for this unsatisfactory result is to be found in the unsuitable arrangement of the plant.

The electric furnace is at a considerable distance from the converters and is separated from them by a long open-hearth furnace plant with five furnaces. The ladle filled with molten converter metal must be carried by means of the crane through the whole open-hearth furnace plant where there is always

some delay so that much time is lost. Moreover, this ladle cannot be brought directly to the electric furnace but its contents must first be poured into another ladle in which it is brought to the electric furnace.

The *cost of operation* at the steel works in Friedenshütte is given in Table IV.

TABLE IV. COST OF REFINING PER TON OF STEEL.

	Kilograms of material used.	Price per ton of material in dollars.	Price per ton of finished electric steel.
Molten converter steel.....	1000	.....	.....
Ore (Krivoi-Rog)	25	7.20	0.18
Lime	30	3.	0.09
Sand	3	0.50	0.005
Fluorspar	4	6.55	0.0275

Fine clay	4	3.75	0.015
Dolomite mass	15	8.50	0.1275
Chamotte	4	4.375	0.015
Carbon electrodes	5.70	72.50	0.4125
Nipple	...	0.515	0.03
Wages (six men, namely two melters, one ladle man, two slagmen and one man at the furnace doors)	...	.....	0.45
Electric energy, (270 kw-hours at 0.625 cent).....	...	.....	1.6875
Amortization (10%) and interest (5%) of $25,000....	...	.....	0.375

Total cost of refining per ton of finished electric steel, $4.20

For these reasons there are long intermissions between the different charges. These intermissions are generally one hour. In this time the furnace cools off and the next charge is delayed. The converter metal is charged rather cold into the furnace.

Further, completely finished converter steel is poured into the electric furnace after manganese alloys have been added to it for deoxidization; as already mentioned, the metal contains 0.4 to 0.5 per cent manganese which must be removed in the electric furnace with a great waste of time and energy. It would be much better to charge the electric furnace with converter metal before manganese alloys are added.

On account of these disadvantages only five charges and surely not more than six charges can be finished during a day, while with a well regulated operation and without any unduly cooling of the furnace and without delay in the transport of the metal, seven or even eight runs could be easily made per day. Under such conditions the cost of refining would be reduced to $3.75 per ton approximately.

With such a low refining cost (which is chiefly a result of the low rate charged for electrical energy in Germany) it is possible to produce very pure steel economically. But it is necessary that the electric furnace be placed right near the converter plant and that it be designed for the same capacity as the converter, that is, if the converter has a capacity of 12 tons the furnace must have the same capacity. The design of a 12-ton Nathusius furnace is given in Fig. 4.

Of all proposed electric steel furnaces the Nathusius furnace must be recognized to be most suitable for simultaneously heating the slag, the bath, and the bottom, and for this reason as well as on account of the possibility of regulating the effect of heating from the bottom electrodes, the Nathusius furnace is worth the careful attention of metallurgists.

St. Petersburg, Russia.

The Use of Anti-Piping Thermit in Ingots.*

BY DR C. CANARIS

Anti-piping thermit is used to improve the quality of steel ingots by reducing the following defects:

1. Shrinking holes and piping.
2. Injurious segregation in the top of the ingot.
3. Large blow holes.

Furthermore the number of the small blow holes is reduced and the resulting material made much denser.

The anti-piping thermit process is based on several patents belonging to the firm Th. Goldschmidt A. G. in Essen, of which the German patent No. 159,757 is the most important. The thermit used as anti-piping thermit in steel ingots consists principally of a mixture of metallic aluminum and iron oxide in equivalent parts. If this mixture is brought to a temperature of over 1200 deg. C. (2200 deg. F.) the iron oxide is reduced by the aluminium according to the well-known equation:

$$3\,FeO + 2\,Al = 3\,Fe + Al_2O_3$$

During this reaction a large amount of heat is set free, which brings the products of the reaction to about 3000 deg. C. (5400 deg. F.). The anti-piping thermit is applied in sheet iron cans as shown in Fig. 1. By means of a thin iron rod, inserted in the hole in the can (Fig. 2) —in most cases a scrap rod of about 10 mm (½ in.) diameter is sufficient—the anti-piping thermit can is introduced into the liquid metal at the point where the reaction is to take place.

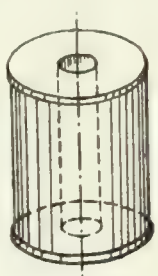

FIG 1

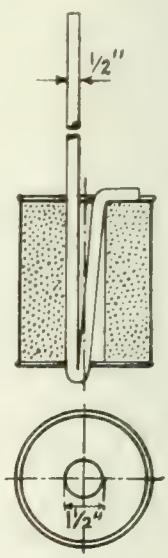

FIG 2

APPLICATION OF ANTI-PIPING THERMIT.

Some years ago many experiments with the anti-piping thermit have been made at different plants, but to the best of my knowledge these were only tried on silicon-treated material, especially forging steel, and never to material not treated with silicon. The purpose of these experiments was to decrease the piping by introducing the thermit cans into the heads of the ingots directly after pouring, allowing the reaction to take place there. It was thought that through the absorption of the heat produced during this reaction the heads of these ingots would be kept hot and the piping thus reduced. A. Obholzer has published a detailed report regarding these experiments. (*Stahl und Eisen*, 1907, July 31, page 117; Aug. 7, page 1155.) From this report it can be seen that the improvement caused by the application of the anti-piping thermit for heating the heads of the ingots is very small and not in proportion to the expenses involved. The reason is that the heat produced by the thermit reaction was altogether too small to increase the temperature of the ingot heads effectively and that extraordinarily large quantities of thermit would be necessary to produce sufficient heat.

The methods were, therefore, changed and the thermit can was introduced at a fixed time after the ingot had been filled. The can was pushed down as far as possible in the mould, preferably clear to the bottom, so that the reaction might take place at the lowest possible point. In this way, as explained hereafter, a strong mechanical effect is exercised on the liquid metal in the interior of the ingot. Special additions to the anti-

* Translated from *Stahl und Eisen*, February 22.

piping thermit are made with the idea of decreasing the melting point of the slag, and thus entirely preventing particles of slag from remaining in the body of the ingots. This improved process was first applied only to silicon-treated material and good results were achieved in several steel works. Encouraged by these results I decided to use the anti-piping thermit also for connection with soft steel not treated with silicon.

As the results obtained were favorable from the first a systematic development of the process was carried out. On the basis of a great number of experiments made with ingots, weighing from 1 ton up, the quantity of thermit sufficient for each weight of ingot was accurately determined. It was then determined experimentally at what time, after pouring the ingot, the thermit should be introduced, and when more metal should be added in order to obtain the most favorable result. From these experiments, the following directions for this process may be laid down.

The pouring of the ingots is accomplished in the usual way, either by direct pouring from the top or by the more complicated bottom-pouring method. The filled moulds are allowed to rest until the solidification has so far advanced, that on the walls of the mould a crust of considerable thickness is formed. The required thickness of the crust depends, of course, principally on the size of the ingot. Then the anti-piping thermit can is pushed to the very bottom of the mould and is held there until the thermit reaction has taken place. The reaction results in a sudden and strong seething motion in the iron. After the reaction ceases, the surface of the still liquid material sinks, according to its condition, from 70 to 150 mm (3 to 6 in.), while the solidified walls remain intact. Then enough hot metal is quickly added, by direct pouring from the ladle, to bring the surface of the still liquid interior of the ingot to the same level as the solidified walls. The moulds are then immediately covered and the ingots left to cool.

The effect of the anti-piping thermit applied in this manner is as follows:

The products of the thermit reaction which are formed in the lower part of the ingot, namely thermit iron and slag, have a much higher temperature and are considerably lighter than the surrounding steel. Therefore, they are both driven with great force toward the top. This accounts for the boiling and seething of the steel in the mould previously mentioned. It is evident that this strong boiling has a favorable effect. It serves to mix thoroughly the entire fluid material and the iron at the top which has been cooled considerably by radiation is replaced by hot metal from the interior of the ingot. This tends to prevent to a great extent the formation of piping and is made still more effective by the large amount of new metal added. By this operation the reduction of volume caused through shrinkage and the removal of gases is compensated to such a degree, that very often the excess material is pressed toward the top with sufficient force to lift the cover. The formation of a pipe is, therefore, rendered entirely impossible. Furthermore, a large amount of gas is liberated as it is not necessary to cover the ingots prematurely, a practice generally followed in ordinary practice. A further removal of the gases is accomplished by the strong boiling of the material caused by the thermit reaction.

Where anti-piping thermit is not used, there is a chance that large and small gas bubbles will be caught in the ingot as the metal becomes pasty, thus causing blow holes and porous metal. With the anti-piping thermit reaction, however, all gases are thrown to the top. Furthermore any segregated and deleterious elements in the steel are likewise thrown to the top where they can do no harm.

These actions are favored by the fact that the escape of gas is not prematurely interrupted by the covering of the mould, and in consequence of the addition of a quantity of fresh metal, the head of the ingot stays hot for a considerable length of time. Therefore, one is able to avoid with certainty the piping and occurrence of large blow holes. A material extremely dense and free from gases is obtained. For these reasons the thermit ingots yield a very high output in the rolling mill. For example, plates rolled from thermit ingots can be used practically in their entirety; only small parts of the top and bottom of the sheets have to be scrapped. As the effect of the anti-piping thermit, if applied properly, is absolutely certain, one can figure when using thermit ingots in plate mills on an essentially higher output than when using ordinary ingots.

Scrap plates, which under normal conditions constitute a pretty large percentage, are almost eliminated. The total output is essentially increased; the expenses, however, which are incurred through the use of anti-piping thermit, are relatively small.

In Table I the various sizes of the cans, their price and the weights of the ingots are given:

Table I. Sizes of the Thermit Cans for Various Ingot Weights

Size of Can	Contents kg.	Contents lbs.	Ingot weight metric tons
00	0.65	1.43	1 to 1.7
0	1.3	2.86	1.7 to 3.5
1	2.5	5.50	3.5 to 8.0

Up to the present time I have had no opportunity to treat larger ingots with thermit. However, the firm of Th. Goldschmidt A. G. has provided larger cans for such ingots.

The cost of the scrap rods, used for the introduction of the cans, is almost equalized through the iron resulting from the thermit reaction and taken up by the ingot.

Below are given a few results of the many experiments which were undertaken to establish the effect of the anti-piping thermit. In the first experiments the anti-piping thermit was applied to improve the quality of metal not treated with silicon. From heat 1143 of the July 12, 1911, two ingots of about 5800 kg (12,800 lb.) each were poured. One of the two ingots was treated with thermit in the above manner, while thermit was not used in the second ingot.

The treated ingot was rolled to a plate of 2927 mm (9 ft. 7 in.) width, 19 mm (¾ in.) thick and 9850 mm (32 ft. 3 in.) long. The output amounted to 75 per cent. A test piece taken from the bottom of the plate gave 35.7 kg per square millimeter (50,800 lb. per square inch) and 31 per cent elongation; one from the top, 37.6 kg per square millimeter (53,500 lb. per square inch) and 29.5 per cent elongation; the lap at the top of the plate was 250 mm (10 in.).

The ingot not treated with thermit was rolled to a plate 3070 mm (10 ft. 1 in.) wide, 23 mm (⅞ in.) thick and 6340 mm (20 ft. 8 in.) long. The output was 68 per cent. The tensile test piece from the bottom showed 35.3 kg per square millimeter (50,200 lb. per square inch) and 33 per cent elongation; while the tests from the top of the plate showed 38.6 kg per square millimeter (54,900 lb. per square inch) and 25 per cent elongation. The lap was 600 mm (24 in.) long.

Further results are given in Table 2 (p. 234); the ingots mentioned were poured from the bottom in one lot. The analysis shows the great uniformity of the thermit-treated material. Table 3 shows a few analyses of the results with the corresponding tensile tests.

Table III. Analyses and Tensile Tests of Thermit Plates

	Analysis — Head				Analysis — Base			
Plate	C%	Mn%	P%	S%	C%	Mn%	P%	S%
1	0.082	0.40	0.022	0.040	0.078	0.40	0.019	0.038
2	0.072	0.49	0.048	0.046	0.070	0.48	0.033	0.040
3	0.076	0.45	0.028	0.020	0.070	0.43	0.026	0.018
4	0.071	0.47	0.040	0.030	0.069	0.45	0.032	0.026
5	0.082	0.45	0.028	0.020	0.074	0.43	0.026	0.018

	Corresponding Test Pieces — Head		Base	
Plate	Tensile Strength in lb. per sq. in.	Elongation %	Tensile Strength in lb. per sq. in.	Elongation %
1	53,893	28.0	51,476	30.5
2	53,609	29.5	51,476	32.0
3	54,320	27.5	51,192	31.5
4	52,329	28.5	49,912	32.0
5	54,889	26.5	51,334	31.0

A great many experiments of this kind were made and always with the same results. In no case was any extensive

piping found and the segregation was comparatively small, although the plates were used with the least possible amount of cropping. These favorable results led to the treatment of a great number of ingots of various weights with the anti-piping thermit in order to get a good average result.

During the time from July 12 to October 31, 1911, 4409 ingots, weighing from 1 to 8 long tons, were treated with anti-piping thermit. The cost of this treatment amounted to 35 cents per ton of ingots. All ingots treated with anti-piping thermit were rolled. These ingots were in all cases 3 to 5 per cent lighter than those ordinarily used, for the same sized plates. Of the 4409 ingots rolled to plates only sixteen showed any defects, which could be traced to a faulty quality of the material. The total weight of the ingots from which these sixteen plates were made, amounted to 22½ long tons; the total weight of the 4409 ingots was 7628 long tons. The loss was thus less than 0.3 per cent, which is extremely low. The total increase of output was more than 5 per cent of the quantity charged.

Table iv gives the weights of the treated ingots and the cost of the applied thermit.

Table IV.

No. of ingots	Weight ingots on long tons	The total weight of 4409 ingots from 391 heats was 7628 long tons they originated Cost of treatment
		Mks.
2134	1.0 to 1.5	2869 anti-piping cans with No. 00 = 5451.10
1200	1.5 to 2.0	
532	2.0 to 2.5	
206	2.5 to 3.0	1302 anti-piping cans with No. 0 = 4296.60
157	3.0 to 3.5	
72	3.5 to 4.0	
70	4.0 to 4.5	238 anti-piping cans with No. 1 = 1511.30
23	4.5 to 5.0	
6	5.5 to 6.0	
9	7.5 to 8.0	
4409		Total mks. 11259.00 = $2,815

If we figure the difference between the price of the plates and the price for the scrap at $15 per ton, the use of thermit ingots for the plate mill will permit a saving of $76.28 \times 5 \times 15 = \$5,720$, while the steel works only expended $2,815 for thermit. The net gain amounts to $2,905 or about 38 cents per long ton.

Added to the above saving are other great advantages which cannot be put down in figures, namely the increase of the production without enlarging the works and the decrease of the resulting scrap. It ought to be further considered that on account of the almost entire absence of scrap plates the work in the rolling mill is much more uniform, as there is no delay in the work and in the filling of orders due to cutting and cleaning of scrap plates. Finally the undoubted improvement in the quality of the steel should not be lost sight of.

The anti-piping thermit process has shown itself as an extraordinarily simple and effective help in improving the quality of soft steel ingots untreated with silicon. Whether it can also be used for silicon-treated metal and just how it is to be applied in such material, experiments which are now being conducted, will show.

Up to the present time only the Harmet pressing process has been used on a large scale for material untreated with silicon. For the application of this process a very large investment is required; and it is so complicated that only a small part of the total production of a mill can be treated. Furthermore, the moulds used in this process have to be more conical in shape than usual, and in consequence of this the Harmet ingots yield a very high percentage of scrap, from the edges of the plates. This practically eliminates all the advantages gained by this process. Regarding the effect of the pressure, I do not think that any transference of the segregation in the ingot to the top takes place.

The anti-piping thermit acts in a manner all its own and is much superior to the Harmet process in every respect. For its introduction no investment is necessary. Its application is very simple and its effect certain. The cost of the anti-piping thermit is low and the benefit of its use can easily be figured in dollars and cents.

Table II. Results Obtained with Anti-Piping Thermit

Liquefied Natural Gas.

The Bureau of Mines has just issued Technical Paper No. 10, entitled "Liquefied Products from Natural Gas; Their Properties and Uses," by Irving C. Allen, and George A. Burrell. The authors endeavor to show how natural gas, which is being allowed to escape almost without restraint in almost all of the petroleum fields of the country, may be conserved.

The authors in outlining their investigations, say: "By fractionating natural gas, either during or after liquefaction, four products can be commercially obtained. Roughly, these four products may be described as follows: (1) The gaseous product, the common natural gas of commerce; (2) the semi-liquid product, known as the new 'wild' product, which should be used only as a liquefied gas and should be held in high-pressure steel containers only; (3) the light liquid product, or light gasoline used for blending with heavy naphthas; and (4) the heavy liquid product, or ordinary high-grade gasoline.

"The possibility of handling the second product in the way that Pintsch and Blau gases are handled, enabling small towns, hotels and country estates to have the advantage of gas illumination, manifestly opens a new field of comparatively great importance in the natural gas industry and should add materially to the investments made in the so-called 'natural gasoline' industry.

"The liquefaction of gases by pressure is not a new industry, but only recently has its application to natural gas been recognized as practicable.

"Up to the last two years the general practice in the manufacture of liquid natural gas was to make the product by compression of the gas in single-stage compressors operated at a pressure of 150 to 300 lb. per square inch. The one product obtained, so-called 'natural gasoline'; was run into a tank and 'weathered.' The weathering consisted in allowing the lighter portions to volatilize spontaneously and escape into the open air until such time as the boiling away of the liquid had practically ceased. Thus the process involved a loss of 25 to 50 per cent, or even more. This loss was an absolute waste, not only of power and of cost of operating the engines and compressors but of the product itself.

"The next step in the industry was to pass the waste gases (of which only the small quantity used for power had been utilized) from the single-stage compressor through a higher-stage compressor, thereby getting a second and more volatile

product—a 'wilder' liquid—which was run back into the first and mixed with the first or heavier condensate. This mixture was then again weathered to a safe degree, whereby it lost the greater part of the more volatile product that had been condensed in the second stage.

"Recently the process had been improved another step, in that the first stage compressor product is run into one tank and handled as ordinary gasoline; the second compressor product is run into a second tank and handled as a lighter gasoline, with which the heavy refinery naphthas can be enriched or enlivened.

"The last-mentioned method of using the second stage compressor product should receive wide recognition, and a market for the product should develop that would be no mean factor in the industry. Blending in the proportions of, say 1 part of the product to 4 or 5 parts of the refinery naphthas makes these heavy naphthas more volatile and of greater value as fuel for automobiles; it also greatly increases their general usefulness. The proportions to be used in blending, however, must be determined more definitely by test.

"The natural gas of this country frequently contains light products that do not condense in the second-stage compressor, and for which it is practicable and necessary to install three, four, and even higher stage compressors. These light products —true gases at ordinary temperatures and pressures—can be compressed and liquefied, but the liquid gases so obtained must be handled as gases and not as oils.

"The mistake heretofore made in the 'natural gas gasoline' industry, as some have recognized, has been the attempt to handle the light gaseous products as oils and not as gases. Until the manufacturers of this lightest third or fourth stage compressor product recognize its gaseous nature, the absolute necessity for insuring the safety of the public involves certain restrictions in its transportation, and not until the realization that this extremely volatile liquid should be handled only in strong steel containers capable of withstanding high pressures will it be transported with safety."

Copies of this paper may be obtained by writing to the Director, Bureau of Mines, Washington, D. C.

Concentration of Ore Slimes by Centrifugal Separation.

It has long been recognized that the great deficiency in ore dressing methods lies in slime concentration. The invention of the Wilfley table and the subsequent development of many similar types of reciprocating concentrators, may be said to have given us high efficiency in the separation of pulps ranging in size from 12 to 60 or 80 mesh, but equivalent progress in slime concentration has not been evident.

Inventors of successful concentrators of coarse pulps have turned their attention to the problem of slime concentration, but they have usually worked along the lines which have proved successful in coarse concentration, and the machines thus evolved can hardly be said to have filled entirely the requirements of treating pulps as fine as 150 and 200 mesh.

The belt vanner and the stationary canvas table also are in use as slime concentrators, but their capacity is low, and thousands of square feet of cencentrating surface is required for even moderate efficiency. In fine, the great demand for the successful slime cencentrator has not yet been met, and consequently the ore dressing industry continues to sustain a loss which, in the aggregate, is enormous.

In our issue of January, 1912, page 3, editorial mention was made of "another and more logical way" in which the slime problem was being attacked by the Anaconda Copper Mining Company, at Anaconda, Mont., and the Cananea Consolidated Copper Company, at Cananea, Mexico. The statement had reference to the experimental tests of the Peck centrifugal ore separator, patented by Philip F. Peck, of Chicago, Ill.

Although no data have been made public regarding these tests, it is understood that the centrifugal machine has proved more successful in handling slime at these places than has any other form of mechanical device. The difficulty of the problem will be understood from the fact that the pulp is finer than 200 mesh. Although it contains as much as 2.75% copper, it has been almost worthless, and has been impounded anticipating the day when some successful means of treatment would be found. It is reported that the Peck centrifugal con-

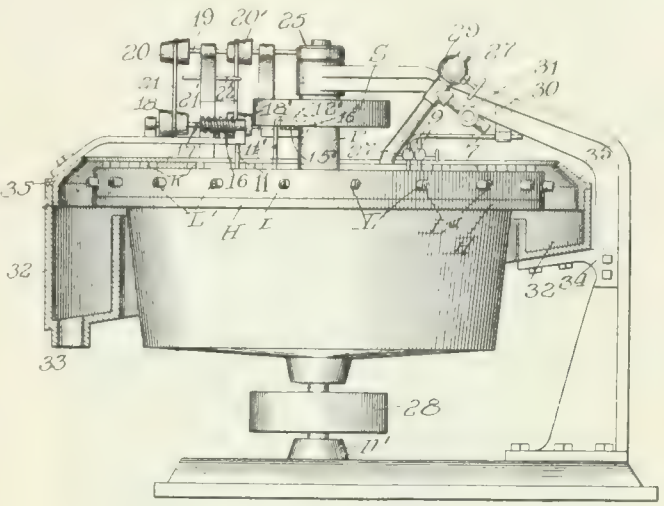

FIG. 1.—GENERAL VIEW OF PECK CENTRIFUGAL SLIME CONCENTRATOR.

centrator has successfully treated pulp of this kind, producing a concentrate containing from 10 to 13% copper, representing a recovery of 83%. This is an important development, and the machine would appear to be worthy of consideration.

Inasmuch as no information is given out by either the inventor of the machine or those who are experimenting with it, we are unable to describe an actual installation. The following description, however, is based on the specifications of patents issued to the inventor. These patents date from Feb. 25, 1908, to Dec. 19, 1911, and are numbered as follows: 879,893-4, 917,120-1-2-3, 981,679-80-1-2, 1,011,077-8, 1,012,097. The first two specifications apparently relate to a design for continuous operation, while the last eleven have reference to a cyclic operation. It is understood that a machine operating on

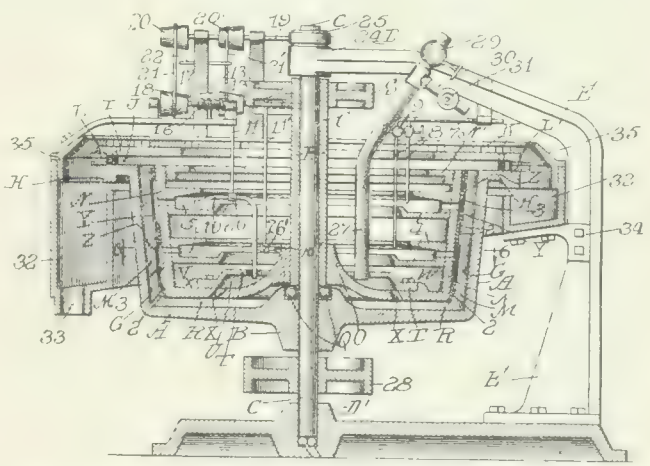

FIG. 2.—CENTRAL VERTICAL SECTION OF CENTRIFUGAL SLIME CONCENTRATOR.

the latter plan is the one now in use, and the following description will have reference to that type.

The machine consists essentially of two truncated cones, one within the other, revolving about the same axis, though at different speeds. The narrow space between the inner and outer cones is the concentrating space. The slime pulp is fed

into this space, where the heavy mineral becomes bedded on the inner surface of the outer cone, which is moving more rapidly than the inner cone. The lighter, or gangue slime rises to the top of the space, and is discharged through small openings in a number of agate cylinders into an annular launder. When the bedding operation is complete, and the gangue slime or tailing has been removed from the concentrating space, a slight water wash is automatically admitted for the purpose of removing a middling product from the surface of the concentrate; and finally, when the middling has passed out into its launder, a flood of water is admitted to scour out the concentrate which is similarly discharged into a separate launder. During the period of discharging the concentrate the speed of the outer cone is reduced to that of the inner.

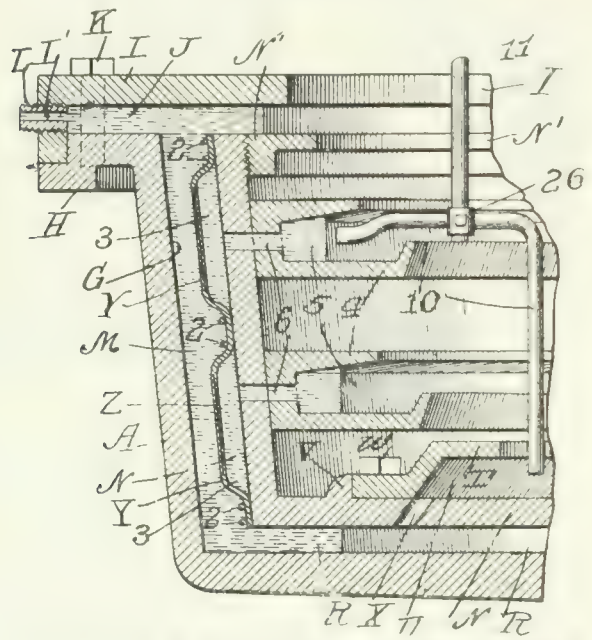

FIG. 3.—DETAIL OF SEPARATING PASSAGE SHOWN IN FIG. 2

Thus the operation is cyclic; and all the phases, such as feeding the pulp, discharging tailing, middling and concentrate, etc., are automatically controlled by a set of cams on a mandril driven by an independent motor. The annular launder also is automatically raised and lowered to correspond with each phase of the cycle, so that the different products are discharged into separate compartments thereof.

The space between the two cones is kept constant during the successive phases of a cycle by means of an elastic medium encircling the inner cone. This elastic medium is adapted to be distended by water while the bed of concentrate is forming, and can be contracted as the concentrating space fills. The admission and discharge of water for this purpose is automatically controlled to correspond with the cycle through which the operation extends.

Apparently the phases of a complete cycle will vary according to the material treated, depending, say, on the ratio of concentration; but once the duration of a cycle is properly determined for any pulp, the various phases may be automatically controlled.

With this general idea of the process in mind, attention may be directed to more specific description of the machine as given in the patent papers. Reference will be made to different figures in order to describe different parts which may be shown plainly in those figures; but it will be understood that a completed machine is supposed to embody the parts described, even though those parts do not appear in each figure.

Figs. 1 and 2 represent respectively a general view and central vertical section of one type of centrifugal separator. Referring to Fig. 2, the separating surface is shown at G, being the inner surface of a vessel A which is closed at the bottom and substantially open at the top. It is rigidly attached to a central shaft C. A ring I (better shown in Fig. 3) is attached to the vessel A in such a manner as to form an annular space J. The depending part of the ring I is provided with a row of screw-threaded holes into which are screwed agate plugs L having openings L', for the discharge of the various products of concentration. A launder 32 surrounds the machine in a position adapted to receive the discharged products. In this figure the launder is shown without separate compartments which appear in other figures.

Within the vessel A is located a second vessel N, some details of which are more clearly shown in Fig. 3. The outer wall of the vessel N is concentric with the inner wall of the vessel A; and between these two surfaces is the concentrating passage M. The inner vessel is attached by hub O to a sleeve P mounted rotatably on the central shaft C. Thus the inner and outer vessels may be rotated independently and differentially as desired, the shaft pulley for the outer vessel being shown at 28, and the sleeve pulley for the inner at S.

The inner vessel embodies, in addition to the rigid part N, a flexible member Y (Fig. 3) made of rubber or similar fabric, securely and appropriately fastened to the inner vessel. The object of this flexible covering is to provide means of controlling the width of the separating passage between the two vessels, in order that the surfaces may be maintained in comparatively close proximity. For example, when the feed is first admitted into the machine, it is desired to have the separating passage narrow to facilitate the bedding of the concentrate; but it is also desirable to widen the separating passage as the bed of concentrate thickens on the surface G. Therefore means are provided for periodically expanding the flexibile member by liquid pressure, and alternately contracting it by removing the liquid.

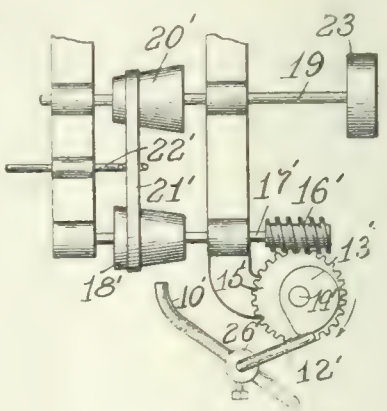

FIG. 4.—DETAIL OF CAM ARRANGEMENT.

In Figs. 2 and 3 are shown the details whereby this contraction and expansion is obtained. The inside of the inner vessel is provided with annular troughs 4 adapted to receive liquid into their channels 5, through pipes 8. Around the troughs are bored holes 6 connecting the channels with the expansion chambers 3, so that when the machine is in operation water will be driven by centrifugal force into the expansion chambers 3, and distend the flexible member toward the concentrating surface G.

As stated before, it is advantageous that the expanding pressure on the flexible member Y be diminished gradually as concentrate accumulates in the separating passage. Wherefore, scoop conduits 10 are supported on rods 11 as shown, and adapted to be moved by cams 13 into or out of contact with the surface of the water in the channels 5. These scoop conduits may thus be used to remove water from the expansion chamber, allowing the latter to contract at the proper time. The water thus removed may flow downward into the feed compartment U and join the feed, or may be forced upward through a pipe and out of the machine as shown in another design. A top plan view of the cam arrangement is shown in Fig. 4. The cams are rotated by worm gears controlled by cone pulleys driven from the central shaft C; although it is understood that in the machines now in operation, these cams and all other means of controlling the pulp, water, launders, etc., are operated independently of the means used to revolve the two cone-shaped vessels.

With this description of the parts in mind, the operation of

the machine during one cycle will be understood, as follows: The outer vessel A is revolved at a desired rate of speed, which is greater than that at which the inner vessel N revolves. The flexible covering Y of the inner vessel is expanded by water so that it approaches within a short distance of the surface G, in order to cause a liquid scouring or washing of the separating surface, or of the concentrate which later accumulates there.

Slime pulp is fed into the machine through the pipe 27, the

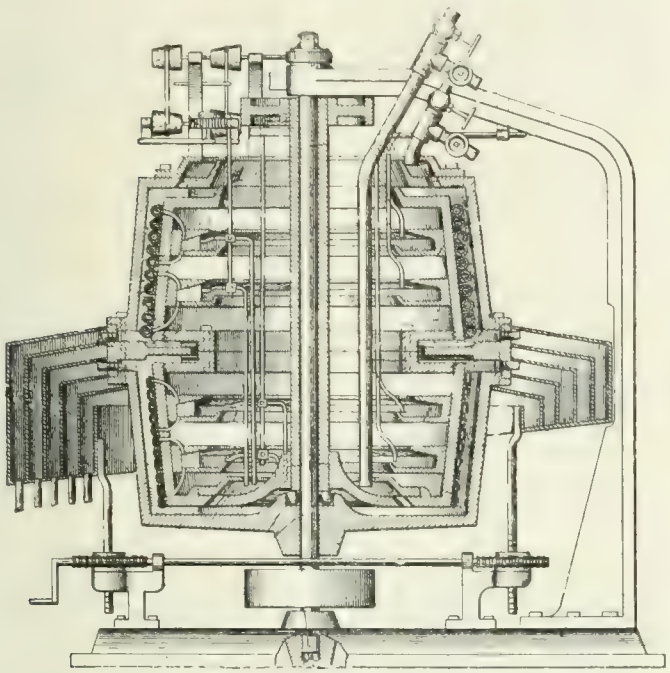

FIG. 5.—MODIFIED FORM OF CENTRIFUGAL CONCENTRATOR.

flow being controlled at the valve 29. It passes into the annular feed chamber U, thence through passages X, and outward and upward into the passage M. As the operation proceeds and concentrate begins to bed on the separating surface, the scoop conduits 10 are moved by their cams so that they gradually remove water from the channels 5, and allow the flexible member Y to contract. This continues until a bed has formed thick enough practically to fill the separating passage. During the bedding process, the tailing has been rising through the separating passage, flowing out of the machine through the openings in the plugs L into the annular launder.

The flow of feed is then cut off at the valve 29, the speed of the outer vessel is reduced somewhat, while that of the inner is maintained, and clear water is introduced through a branch pipe 30, controlled by valve 31. By this time the cams have moved the scoop conduits so as to allow a further accumulation of water in the channels 5, which distends the flexible covering Y. Thus the clean water scours the bed of concentrate, removing a middling product which passes out through the same openings L^1. Finally, the scouring and washing action is increased, and the bed of concentrate is washed out of the machine and collected in the launder. This completes a cycle of operation. As stated before, the means for governing the various phases of a cycle are automatic in their action, and independent of the means used to rotate the separating vessels.

Fig. 5 illustrates another patented type of separator, which is simply a combination of upper and lower separators having the same cycle and discharging through a common series of openings. This figure shows the launder compartments for receiving the different products of the machine, and means (not automatic) for raising and lowering the launder to bring the proper compartment into juxtaposition with the openings.

Fig. 6 illustrates a combination which includes automatic means for controlling the phases of a cycle, such as introducing pulp and wash water; admitting and removing compression water from the flexible chamber; and raising and lowering the launders to permit the different products to be collected separately. The arrangement appears rather complicated, but it must be remembered that there are several parts which must work in phase in order that the cyclic operation of the machine can continue uninterruptedly. Although this figure shows the governing means to be actuated by the same power that drives the separating vessels, it is understood that in the working machines the different phases of a cycle are controlled from an independent source of power.

In Fig. 6 the launders are moved into the desired positions by means of the wedges 114, which are operated by the hydraulic piston 119, which, in turn, receives water from the 4-way

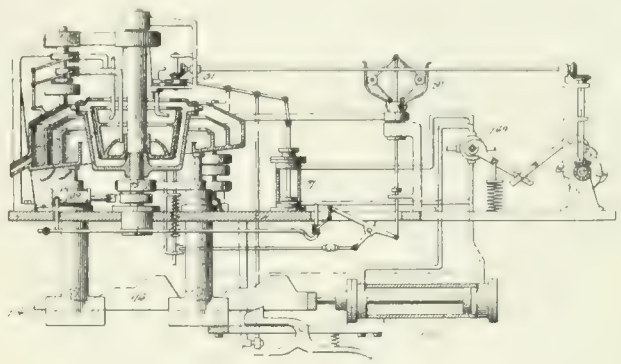

FIG. 6.—DETAIL OF MECHANISM GOVERNING AUTOMATIC REGULATION OF CYCLES OF SEPARATION.

valve 149. The feed of slime pulp and wash water is controlled by the lever 146 attached to the launder. The cams governing the scoop pipes which remove compression water from the channels leading to the expansion chamber are shown at 31, and are actuated by the hydraulic piston 71, which also receives water from the 4-way valve 149. The action of the hydraulic piston 109, which is controlled by levers attached to the governor 91, moves a brake 75 which, at the proper time, reduces the speed of the outer vessel.

The foregoing description gives, in brief, the principles on which the Peck centrifugal slime concentrator operates, although the actual mechanical means of accomplishing the operation may be different from those given. The fact that the machine has been tested with apparent success leads to the hope and belief that it may prove to be the slime concentrator for which there is such a demand; and the publication of authentic details of actual practice will be awaited with interest.

Vanadium and Dynamic Steel Tests.—*American Vanadium Facts,* Vol. II, 1, just issued by the American Vanadium Company of Pittsburgh, Pa., contains a quite interesting article on mechanical tests of steel. In these days of alloy steels a determination of the maximum breaking strength and percentage of stretch at rupture no longer suffice, but "dynamic" tests become important. Woehler, in the middle of the last century, devised a method which showed that metals will fail from fatigue or gradual fracture when subjected to repeated stresses well within their breaking strength. Prof. Arnold in Sheffield devised a modification of Woehler's test. It was intended as a shortened Woehler test to determine the same property of steel as is determined by the latter. But it was found that Arnold's test predicted liability to fracture from causes altogether apart from Woehler's fatigue phenomenon, and registered potential brittleness, which the Woehler test not only failed to detect, but emphatically pronounced absent. The whole matter, while generally of great importance for testing and designing engineers, is especially interesting in connection with vanadium steel, as vanadium is now looked upon as the element par excellence which greatly increases the elastic limit and dynamic strength of steel without impairing its ductility.

Radiation Pyrometry.

By G. A. Shook.

I. Radiation Laws.

There are today four precise laboratory methods for measuring high temperatures.

Electric-resistance Pyrometer.—In this pyrometer use is made of the variation of the electric resistance of metals with change of temperature. Since resistance can be measured with extreme precision, the method permits of very precise measurements of temperature up to 1000° C.

Thermoelectric Pyrometer.—It utilizes the variation of the e.m.f. with temperature developed at the junction of two dissimilar metals. This pyrometer may be used for temperature up to 1600° C., when the thermo-couple consists of wires of platinum and platinum-rhodium or iridium.

Total Radiation Pyrometer.—In this type of pyrometer the total radiation from hot bodies is taken as a measure of their temperature. This instrument requires a device for determining very small changes in temperature, and does not admit of very great accuracy, but is very convenient for very high temperatures.

Optical Pyrometer.—In the case of pyrometers of this class, temperature estimation is made by means of a photometric comparison for a particular wave length, between the radiation from one standard lamp and the radiation emitted from the body under observation. This is a very precise method and is available for the highest known temperature.

TEMPERATURE SCALES.

Temperature is generally measured by the magnitude of some physical change produced in a body by heat, such as the expansion of mercury in the ordinary mercury-in-glass thermometer, change of electrical resistance, in the resistance thermometer, or the production of an e.m.f. in the the thermo couple.

In order that the different thermometers may be comparable, they are generally standardized by means of invariable and easily reproduced fixed points, and the two universally employed are the temperature of melting ice and the temperature of boiling water. The interval between the fixed points, may be subdivided into any convenient number of divisions, each of which will represent one degree of temperature.

In the centigrade scale, the zero is arbitrarily taken as the melting point of ice, and the interval divided into 100 parts.

Clearly the magnitude of a division will depend upon the substance employed and the temperature change from 1 to 2 may not be the same as the temperature change from 50 to 51. The zero point on the centigrade scale, does not, of course, mean that there is no heat present when the mercury stands at zero.

Since the expansion of air is about twenty times as great as that of mercury, some form of an air thermometer is generally used for accurate scientific purposes. From the law of Charles, the volume of a given mass of gas, under constant pressure, increases by a constant fraction of its volume at zero for each rise of temperature of 1° C. This law leads to an absolute scale of temperature. According to Boyle's law, the product of the pressure and volume of a gas at constant temperature, is a constant. A combination of these two laws gives the "gas law" $pv=RT$, where T=absolute temperature (°C+ 273°). The absolute zero is 273° below the arbitrary 0°C.

Until recently, all "temperatures" in precise work where referred to the international Normal Scale of the constant-volume hydrogen thermometer.

It must be remembered, however, that these gas laws are not rigorously true for real gases, such as CO_2, H, and N, so that different gas scales will differ slightly among themselves, and furthermore, no one gas is satisfactory throughout the entire range of temperatures which are used in gas thermometry.

Hydrogen can be used for very low temperatures, but above 300° C it is unreliable. Nitrogen, on the other hand, cannot be used for low temperatures, but is suitable for high temperatures. In the absence of a perfect gas, we have practical standard gas thermometers, such as hydrogen and nitrogen, for which thermodynamic corrections have been determined. In practice, however, the gas thermometer is never employed, by reason of the difficulties inherent in its use, and furthermore, because there are numerous other thermometers more convenient which can be compared with the gas thermometer.

A theoretical thermometer scale, independent of any substance used, has been worked out and it is known as the "thermodynamic scale." It can be easily shown that this scale agrees with the perfect gas scale. In exact work, it is necessary, therefore, to define temperature in terms of the thermodynamic scale rather than the "normal" or "gas scale." Especially is this true in the case of radiation pyrometery where the laws and formulas developed, have their foundation on thermodynamic laws.

RADIANT ENERGY

There are three distinct modes of transference of heat, namely conduction, convection, and radiation.

In conduction, heat is transferred from particle to particle of a body as in the case of solids. The conduction of heat along an iron bar is a familiar example.

In convection, heat is taken up by matter and carried with it in its motion. It can be shown experimentally that in the case of liquids and gases, which are poor conductors, heat is transferred by the motion of sensible masses of matter.

Heat may also be distributed as radiant energy, just as light is propagated. While it was formerly supposed that luminous bodies give rise to three distinct kinds of radiation; luminous, heat, and actinic, it is now universally known that the three are identical. There is no simple theory of radiation which will explain all the phenomena satisfactorily. The electron hypothesis will, perhaps, give us the best physical conception.

In order to account for the more complex phenomena that are constantly appearing in physics and chemistry, we must imagine that the chemical molecule or atom consists of a nucleus of positive electricity in equilibrium with particles of negative electricity or "electrons." The mass of an electron has been found to be about the 1/1700th part of the mass of the hydrogen atom. As long as an atom remains intact, it is electrically neutral, but when an electron escapes from it, it becomes positively charged.

Now we imagine that any charged body has "electrical lines of force," emanating from it, and terminating on some other body of opposite charge, and, further, that a moving charge. such as an electric current in a metallic conductor, maintains a constant magnetic field about it. This magnetic field changes in direction and magnitude as the velocity of the moving charge changes. Now, while the theory is very complex, it is easy to see that when an isolated moving charge, with its lines of force emanating in all directions, is suddenly brought to rest, some sort of a disturbance must be propagated along the lines of force. This disturbance is most effective in a direction perpendicular to the motion of the moving charge.

Let e, Fig. 1, represent an electron with its electric lines of force, at rest, and e' the same electron moving to and fro in the direction BB^1. A wave disturbance will be sent out along the lines of force in the second case. It will be a maximum along AA^1 and zero along BB^1. It is this electromagnetic pulse which produces the sensation of heat or light.

If this is true we should expect a magnetic field to produce some effect upon spectroscopic lines, that is, we might expect the "D" line of sodium to broaden, or to shift its position slightly. This magnetic effect has been found by experiment, and this experimental fact is one of the foundation stones of the electron theory.

The manner in which this pulse is produced, affects the quality of the radiation markedly. In the X-ray tube, the free negative cathode particles on being suddenly stopped by a metallic plate give rise to the well known Roentgen Rays. In this case the pulse propagated along the lines of force is very abrupt, because the velocity of the moving charge is abruptly

brought to zero. The moving electron within an atom or from one atom to another does not suffer such a sudden change of velocity and therefore the resulting pulse is much smoother and of longer duration.

Now according to the electron theory, the optical properties of substances are closely related to their electrical properties. A substance which conducts electricity is called a conductor, and one which does not, an insulator, but of course, there is no sharp dividing line. All insulators, in fact, will conduct to some extent at very high temperatures so that in this sense the term "metal" is often applied to any substance which is in any degree a conductor. In the case of metals, electrons are constantly escaping from the atoms, leaving the latter charged. The electron will not leave the metal, however, except at high temperatures. These escaped electrons are in turn being attracted toward positive atoms. It is this change in the electron's

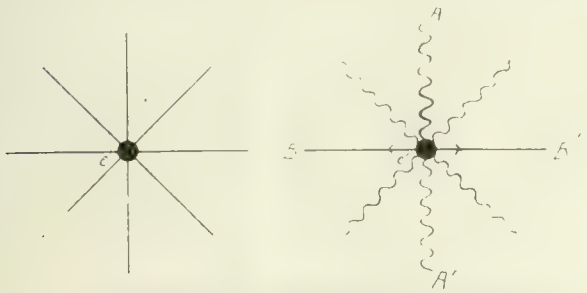

FIG. 1.—ELECTRON AT REST AND IN OSCILLATION

velocity, brought about by its impact with atoms, which gives rise to the radiation that is propagated throughout space.

According to the dynamical theory of heat, any hot body is composed of minute particles, identical with the chemical atom, which are in rapid vibratory motion. When heat is given to a body, the velocity of these particles is increased and its temperature is raised. However, it is the motion of the electrons into or out of the atom, that produces radiation and not the motion of the atom itself. We know of no other radiation except electro-magnetic. Furthermore, if all atoms could emit radiation then any material substance would soon disintegrate, due to the motion of its atoms. In a solid body, the electron may penetrate for a small distance into the atom, and then move away in a different direction, so that the pulse is not so abrupt as in the case of Roentgen rays.

The disturbance sent out from incandescent solids at high temperatures, produces what is known as "white light," which may be resolved into a continuous spectrum (i. e., a continuous band of colors from violet to red) by means of a prism. The energy thus radiated in the form of transverse etherical waves is transformed into heat, whenever the wave disturbance falls upon some material body.

The impinging of these waves upon the retina of the eye, produces the sensation of red light, when the radiating body is about 600° C. Violet light corresponds to vibrations of small periods or short wave lengths, while red light corresponds to long wave lengths.

The visible spectrum occupies a very small part of the entire known spectrum, which extends from wave-lengths of about 0.00001 cm. to 0.03 cm. A unit commonly used to express wave lengths is $\mu = 0.0001$ cm. The visible spectrum extends from about 0.7μ to 0.4μ (Fig. 2).

The radiation sent out by cooler bodies is quite similar to that emitted by incandescent bodies, but the maximum part of the energy is in the region of the long wave lengths, which are not visible to the eye. Nevertheless, it must be remembered, that even at room temperature, radiation corresponding to all parts of the spectrum is being emitted from bodies, only to a much smaller degree.

There are several optical methods for determining "wave-lengths" in the visible part of the spectrum, and the wave-lengths of the most useful emission lines of such elements as mercury, hydrogen, etc., have all been carefully determined. These may be used for calibrating an ordinary prism spectrometer. The wave length of an unknown line may then easily be determined. By means of such a calibrated spectrometer, the mean wave length transmitted by a piece of colored glass may be determined.

When light or heat falls upon any body, it may be reflected, transmitted, or absorbed, or all three phenomena may occur simultaneously. A body which absorbs all the energy, incident upon it, such as lampblack, neither transmitting nor reflecting any, is said to be perfectly *black*. The *emissive power* of a body is the ratio of the energy per square centimeter that it emits at the particular temperature to the energy per square centimeter that a *black body* would emit at the same temperature. Kirchhoff formulated the law that the emissive power, e, of a body equals the absorptive power, a. For a black body, then, $a = e = 1$.

The curves in Fig. 2 represent the distribution of energy of a black body for various temperatures. It is seen, from these

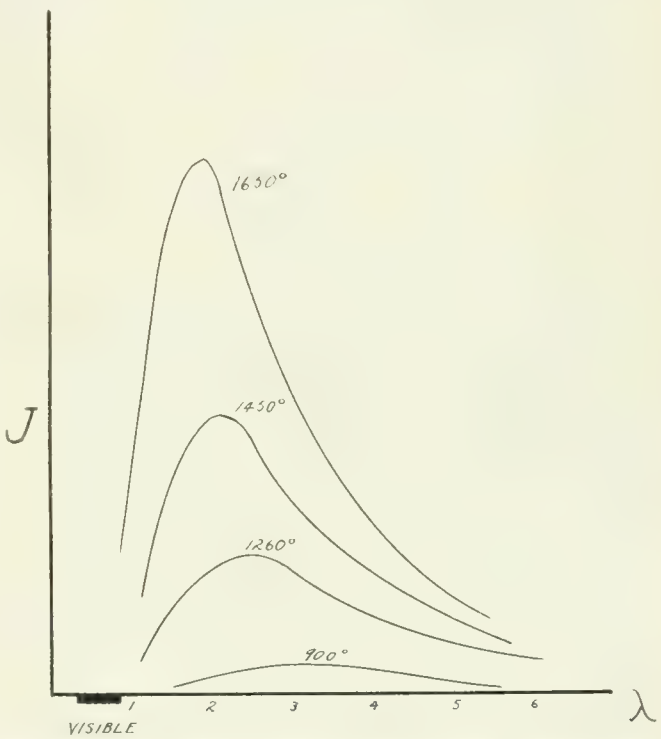

FIG. 2. DISTRIBUTION OF ENERGY RADIATION FROM A BLACK BODY.

experimentally determined curves, that for low temperatures the energy maximum, i.e., the highest point of the curve, is far out in the invisible red. Furthermore, the maximum shifts toward the shorter wave-lengths as the temperature is increased. Now as a black body radiates all the energy incident upon it, or all that it absorbs, since $e = 1 = a$, no other body at the same temperature can radiate more energy than a black body. This is true for any wave-length, as well as the whole spectrum.

A black body, however, would not make as efficient a luminous radiator as some body with an abnormal emission in the visible spectrum and a corresponding suppression of radiation in the infra red. In the case of the Auer (Welsbach) mantle there is practically no emission between 4μ and 7μ.

Again it is seen from the above curves that at high temperatures the relative amount of radiation in the visible part of the spectrum is much greater than at lower temperatures, i.e., the energy increases with temperature much faster in the short wave-lengths than in the long ones. It is for these two reasons that metallic-filament lamps, such as tungsten and tantalum, which can be worked at high temperatures, are more efficient than the carbon lamp. Carbon is approximately a

black body, but a carbon lamp cannot be worked at high temperatures. Platinum, on the other hand, departs considerably from a black body, but it would make a more efficient lamp than any of the metallic-filament lamps if it could be worked at high temperatures.

There is no known substance which is perfectly black, but it can easily be shown that the interior of a uniformly heated enclosure radiates like a black body.

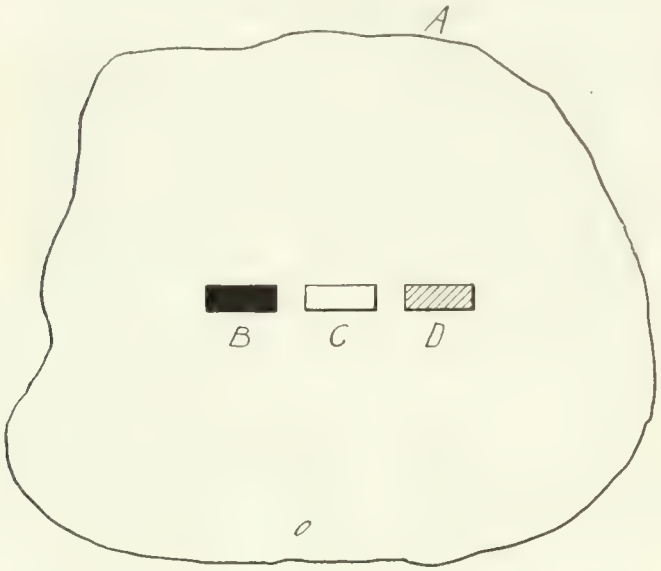

FIG. 3.—BLACK BODY.

Let *B*, *C* and *D* (Fig. 3) represent three bodies of different emissive powers, which are completely surrounded by an envelope *A* maintained at a constant, uniform temperature. We will now suppose that the entire system has come to temperature equilibrium, so that every point within *A* is at the same temperature. Hence *B*, *C* and *D* have the same temperature.

To make the case perfectly general we will make some further assumptions, namely, that *B* is a black body, such as a piece of carbon, therefore its absorptive power is unity; *C* is perfectly transparent, so that its absorptive power is zero, and *D* absorbs one-third the radiation incident upon it, reflects one-third and transmits one-third, i.e., its absorptive power is one-third.

Now, any body placed within *A* will radiate a certain amount of energy; part of it may be transmitted through it, part may be reflected from its surface, and the rest the amount it emits that is proper to itself. For example, if its absorptive power is one-fourth, that means that of all the energy falling upon it, only one-quarter is absorbed, and this one-quarter alone produces heat within the body. The other three-quarters is reflected from the surface, or transmitted through it, so that all the energy it receives it again radiates. We are here considering only the radiation that is purely thermal; that is, chemical effects, such as luminescence, must be excluded.

Let us now consider the relative radiation of the three bodies; that is, let us see how they would appear to an observer at *O*. Since *B* is in temperature equilibrium with the walls of *A*, it must radiate to them as much energy as it receives from them. If it radiated more than it received it would cool down, and if it radiated less it would become hotter than *A*, which is contrary to our assumption that *B* and *A* are at the same temperature. *B* will therefore radiate to the wall behind it as much as it receives from that wall and consequently to an observer at *O*, *B* would appear just as bright as the surrounding wall. Hence the inside wall of *A* will radiate as a black body. Since *C* transmits perfectly, the observer would, of course, see the wall beyond and therefore *C* will radiate as a black body. Now *D* only radiates one-third of the energy it receives, but it allows one-third of the energy falling upon it, from the rear wall, to pass through, and it also reflects from the front wall one-third the incident energy, so that it will radiate as much energy as *A*, *B* or *C*, and will therefore be as bright as *A*. Hence *D* radiates like a black body.

Now, all of the energy radiated by *B* is proper to itself because it absorbs everything and emits just as much as it absorbs. All of the energy radiated by *C* comes from the wall of *A*, and none is proper to itself, since it absorbs nothing. Since all three bodies and the interior wall of *A* all radiate like a black body, it follows that any body with any emissive power whatsoever, within a uniformly heated enclosure, made of any material whatsoever, would radiate as much energy as an ideal black body at the given temperature. To an observer at *O* the interior of *A* would appear uniformly bright and no contour of objects would be perceptible. If all the bodies could be quickly removed from *A* and examined in a darkened room they would present quite different appearances. *B* would apear as bright as it did when within *A*, but *D* would only appear one-third as bright and *C* would radiate nothing whatever and therefore appear black. This is a matter of experience and can be easily verified experimentally. This conception of a black body is very important in the application of pyrometry.

LAWS OF BLACK BODY RADIATION.

Stefan deducted from experiment, and Boltzmann deduced from thermodynamic considerations, the law that the total radiant energy emitted from a black body is proportional to the fourth power of the absolute temperature, or

$$J = KT^4$$

where K is a constant.

Another important law is Wien's "distribution law," which gives the relation between energy and absolute temperature for a particular wave-length, i.e., a particular color of the spectrum. This law does not hold, however, except for high temperatures.

It is as follows:

$$J = C_1 \lambda^{-5} e^{-\frac{C_2}{\lambda T}} \quad . \quad . \quad . \quad (1)$$

J = energy corresponding to wave-length λ.
λ = wave-length measured in μ.
T = absolute temperature = $273 + t$.
C_1 and C_2 = constants.
$C_2 = 14500$ when λ is measured in μ.
e = base of the natural system of logarithms.

Formula (1) may be written in the form

$$Log_{10} J = K_1 - K_2 \frac{1}{T}$$

where

$$K_2 = C_2 \frac{log\ e}{\lambda}$$

hence

$$t = \frac{K_2}{K_1 - log_{10} J} - 273 \quad . \quad . \quad . \quad (2)$$

This equation, which has been considerably simplified, gives the relation between the temperature t in degrees centigrade and the logarithm of the energy and may be applied to any pyrometer using monochromatic light, in which the luminous intensity can be varied in a continuous and determinate manner, as in the Wanner and Le Chatelier.

K_2 can be calculated when λ is known and K_1 is an arbitrary constant depending only upon the units of J. When J is known for some particular value of t, K_1 may be calculated from equation (2).

The methods of applying these two equations to radiation pyrometers will be taken up in a subsequent paper.

University of Illinois,
Urbana, Ill.

Notes on Chemistry and Metallurgy in Great Britain.

(By our Special Correspondent.)

The Growth of Cast Iron.

In a lecture to the Sheffield branch of the British Foundrymen's Association on the 20th February, Professor Carpenter gave the results of his further researches on the growth of cast iron after repeated heatings which had been undertaken with the view of providing a remedy. He found that the substance mainly instrumental in producing the growth was silicon, but the presence of carbon in the form of graphite was necessary before growth could occur. Graphite gave rise to channels through which the gases penetrated and oxidized the silicon; and both with superheated steam and with furnace gases at high temperatures the process of growth was identical. He suggested manganese as a preventive, and, after an extensive series of experiments, was in favor of the use of an alloy containing 1.5 per cent of manganese, 2.5 per cent of carbon, and 0.5 per cent of silicon, the melting point of which was 1345 deg. C.—practically the same as that of a No. 1 hematite containing rather over 4 per cent of total carbon. The sulphur and phosphorus in his test bars were only 0.01 per cent, but the raising of their figure to 0.06 per cent would not make any material difference, would put the metal in the usual grade of English irons, and reduce the melting point to but little over 1300 deg. C.

Electric Smelting.

The progress of the electric furnace in Britain is slow yet steady, and the cost of power supply is the chief obstacle to be overcome before a more rapid advance can be looked for; but that the advance will ultimately take place appears to be beyond question.

At Sheffield Messrs. Vickers, Ltd., are building an 8-ton Héroult furnace of the three-electrode type, which will be the first of its kind to employ three-phase currents in England. The three-phase furnace permitting the use of static transformers with an efficiency of fully 97 per cent should effect a considerable reduction of power cost per ton of steel as compared with a single-phase furnace with a motor generator set with intrinsically much lower efficiency.

The Electric Furnaces and Smelters, Ltd., who have three large furnaces in operation at Luton producing ferro-alloys, chiefly ferro-tungsten, propose to erect two more furnaces each of which will have nearly three times the capacity of the furnace they are now using. In the production of tungsten-steel the 50 per cent ferro-tungsten is preferable to one much richer in tungsten on account of the lower temperature necessary for its solution and the freedom of the steel from hard spots, flaws, etc., resulting from imperfect solution of tungsten. The 50 per cent ferro-tungsten is a true solution of tungsten in iron, while the alloy with a higher tungsten content is a mere mixture of tungsten with such solution; and the undissolved excess of tungsten necessitates raising the steel bath to a considerably higher temperature, and even then is liable to cause defects.

Smelting of Tin.

Very satisfactory results are reported from Cornwall where about a year ago a trial furnace, with a capacity of some 2 tons of ore per day, was erected for the smelting of tin. This work has been described in detail in the issue of September, 1911, of this journal (vol. IX, page 453).

Sheffield Steel and Smoke.

The anti-smoke nuisance agitators are moving strongly just now at Sheffield and are urging the adoption of gas furnaces for reheating; but a considerable number of manufacturers say that smoke is necessary in certain processes.

Professor Arnold energetically supports the manufacturers and asserts that the skilful use of smoke by experienced workmen is largely instrumental in maintaining the famous quality of Sheffield steel. The carbon quality of the steel, he says, depends on having a smoky flame in the reheating furnaces; and it is a matter of the highest importance, because otherwise the surface of the steel would be deprived of the carbon which confers specific properties and would be comparatively useless. The oxidation which would remove surface carbon would, moreover, probably penetrate and cause rottenness in the ingot under the hammer and in the rolls. Steel must not be reheated in an oxidizing or "dry" flame, but with a smoky or "green" flame; and the professor is strongly opposed to the use of gas furnaces because the completeness of the combustion of the gas results in a "dry" flame which does not yield any deposit of carbon. Steels, and particularly hard steels, must be heated in a smoky flame giving a black carbon deposit, and the emission of a dense black smoke is a necessary accompaniment of the early stage of reheating; while as the operation proceeds the regulation of the furnace to avoid excess of oxygen in the flame also renders further evolutions of smoke unavoidable; and the higher the carbon content of the steel is, the greater will be the quantity of smoke required.

M. W. F. Beardshaw, at the annual meeting of the Sheffield Chamber of Commerce which took place early in February, said Professor Arnold deserved the thanks of the manufacturers for the able explanation of the subject he had given to the public. They did not want to make an unnecessary quantity of smoke, but the trade must be protected against interference. Good Sheffield steel stood first in the markets of Europe, and any action which might be prejudicial to the quality of that steel would be disastrous to the industry.

Trade Notes.

The activity in the steel trade in Scotland is indicated by the announcement that the Clydebridge steel works are to be reopened. About four years ago, when the demand for steel was not equal to the supply, these works were closed by an agreement with the Scottish Steelmakers' Association which guaranteed the shareholders 5 per cent on the capital on condition that no steel should be produced for market purposes.

New steel works to have an output of 5000 tons per week are to be put down at once at the Burrows, Swansea, at a cost of between £100,000 and £150,000, by Messrs. Baldwin & Company, who now have extensive tinplate works there. The subsequent erection of blast furnaces is contemplated.

The Knowles Oxygen Company, Ltd., is erecting new works at Bromborough Port, on the Mersey, to be in operation by next October, for an output of 200,000,000 cu. ft. per year of oxygen and hydrogen. The plant consists of two gas engines of 1750 b.h.p. each coupled directly to D.C. generators, and the requisite Mond gas and recovery plant. It is expected that oxygen will be sold direct from the holders at prices ranging down to 5/- per 1000 cu. ft., and compressed in cylinders at £1 per thousand; while the purity guarantee will be raised to 99½ per cent.

Engineering Imports and Exports.

The returns issued by the Board of Trade for January, 1912, show a satisfactory all round improvement on the figures for the same month last year. Imports of iron and steel, including manufactures, reached £1,069,593, an increase of £244,288; and exports were £4,354,238, an increase of £523,551. Imports of other metals, including manufactures, totalled to £2,754,249, an increase of £506,748; while exports were valued at £956,866, an increase of £91,878. Imports of electrical goods amounted to £139,996, an increase of £14,191; and exports are put down at £275,091, an increase of £72,095. Machinery was imported to the amount of £514,947, and exported to the amount of £2,666,642; showing increases of £81,228 and £180,559 respectively. Imports of new shops were only £57—a decrease of £9734; and exports, value £183,222, decreased £46,986.

The Coal Miners' Strike.

The threatened national strike of the coal miners is an accomplished fact, and about 1,065,000 men have ceased work.

The English owners, although unable to concede the unqualified minimum wage for all workers were prepared to accept the principle wherever the conditions of work reduced a man's output. The Welsh miners have unjustifiably broken their unexpired contract; and the failure of any approach to an arrangement in their case is not to be wondered at. There are rumors that the Premier has threatened to introduce a Minimum Wage Bill in the House of Commons next Monday unless the owners give way; but any such measure would not be welcomed by the law-abiding section of the general public, amongst whom the feeling is growing that the refusal of the English miners to accept the fair offers of the owners deprives them of any claim to sympathy. The duration of the strike cannot be very prolonged, for the total of the men's union funds is little if anything over £2,000,000; but even if it last only a fortnight or less its effect on the trade of the country will be disastrous. Iron and steel works, tinplate works, potteries, and factories generally, have already begun to close, and soon millions of workers will be without employment. All trades must suffer severely; and engineering and chemical industries will have to bear a heavy share of the evils resulting from the dissemination of socialistic ideas among the classes whose scanty educational opportunities make them the easy dupes of the professional agitator.

Market Prices.

FEBRUARY, 1912

Copper has shown an upward tendency steadily throughout the month. Starting at just under £62 it had dropped nearly a pound by the 6th, but afterwards rose steadily, and finished at £64.7.6.

Tin has been confined to fairly narrow limits for this market. Starting near £195 it has kept within £3 either way, and closes at £199.

Lead. Inclined to rise. Opened £15.18, closes £16.3.9.

Haematite rose fairly well after the 9th. Opened 62/2; closed 66/-.

Scotch Pig has kept fairly steady, on or about 55/-, closing at 55/6.

Cleveland has been rather stronger at 49/- to 49/6, closing 49/6½.

India-rubber has been fairly quiet. Opening at 4/8 it closes at 4/7½ per lb.

	£ s. d.
Alum, lump, loose, per ton	5.15.0
Antimony, black sulphide powder, per ton	20. 0.0
Borax, British Refined Crystal, per ton	16.10.0
Copper Ore, 10 to 25% per unit	10/10½ to 11.4½
Copper Sulphate, per ton	22.17.6
Carbolic Acid liquid, 97/99%, per gal	1.8
Creosote, ordinary good liquid, per gal	2
Camphor, 1 oz. tablets	1.9½
Caustic Soda Ash, 48% ordinary, per ton	5.10.0
Hydrochloric Acid, per cwt	5.0
Mica, small slab, original cases, per lb	6d. to 2.0
Naptha, solvent 90%, 160 deg. C. per gal	8¾
Petroleum, Russian Spot	8
Quicksilver, per bottle	8. 7.6
Sal Ammoniac, lump, first delivered U.K. per ton	42. 0.0
Sulphate of Ammonia, f. o. b. Liverpool, per ton	14.18.9
Sulphur, recovered, per ton	5. 0.0
Shellac, standard, T.N. Orange spot, per cwt	4. 4.0
Tin Ore, 70% per ton	£124 to 126. 0.0
Zinc, Vieille, Montagne	30. 0.0
Platinum	9. 5.0

The differences in price are therefore as follows:

Higher.

	£ s. d.
Copper, ton	2. 7.6
Tin	4. 0.0
Lead	5.9
Haematite	10
Scotch Pig	6
Cleveland	6/4
Quicksilver, bottle	2.6
Ammonia Sulphate	5.0
Tin Ore	4. 0.0

Lower.

	£ s. d.
Copper Sulphate, ton	17.6
Carbolic Acid, gal	1

The impending coal strike will naturally influence the price of metals.

Synopsis of Current Literature.

Gold and Silver.

Cyaniding at the Talisman Mine, New Zealand.—Some interesting details of tube milling, agitation and filtration are given in an extensive paper on the Talisman mine by Arthur Jarman, in the *Proceedings* of the Australasian Institute of Mining Engineers, Sept. 30, 1911.

The author is not clear as to the grade of ore treated, but from some data given in connection with the mining operations we gather that the ore is comparatively high grade, with a high, but varying, ratio of silver to gold. Part of the ore is oxidized, but occurrences of sulphides of copper, lead and iron are common.

The general plan of mill treatment is as follows: Crushing in Blake crushers and stamps; classification of the stamp product, the coarse sand being re-ground in tube mills and combined with classified overflow; classification of the tube mill discharge, with return of coarse portion to the tubes; amalgamation of fine pulp from tubes; concentration on vanners; leaching of sand tailing and agitation of slime; vacuum filtration; precipitation by zinc shavings; production of bullion.

The tube mills were not part of the original plant, but were installed later. The following grading analyses show the effect of the tubes in grinding.

Mesh.	By Stamps.	By Stamps and Tubes.
+30	0.08	0.00
+40	3.24	0.00
+50	12.37	0.03
+60	6.63	0.30

—200	....	13.10
—200	....	57.24

Two of the tube mills are lined with H. P. Barry's patent sectional honeycomb liner, and one with F. C. Brown's iron plate and rib liner. An opportunity was thus afforded to compare the two under identical conditions. From the point of view of the operator, the Brown liner is better, for should a rib or plate break or loosen, a small leak promptly starts at the bolt holes, thus giving timely warning. With the Barry liner, however, the contents of a quarter sector may be dislodged without the defect being discovered until the mill is opened. The time required for renewing liners is also in favor of the Brown. The following grading tests on the tube mills shows the work of each kind. In studying the table it must be remembered that the tube mill "feed" is composed of the "battery pulp" plus the returned sand from the classifiers following the tubes. The "plate heads" are the overflow from these classifiers.

	Battery	Plate	—Feed—		—Discharge—	
Mesh.	pulp	heads.	Barry.	Brown.	Barry.	Brown
20	7.6	0.02	2.6	2.6	0.36	0.42
40	17.8	0.18	12.3	13.4	7.9	9.0
60	11.4	2.2	24.6	25.7	25.3	25.9

80	8.8	9.6	26.6	28.6	31.0	32.7
100	5.4	11.8	9.6	9.1	9.9	9.1
120	3.0	5.8	3.6	3.1	4.0	3.9
150	3.0	5.6	2.8	2.1	3.2	2.5
Thru 150	42.7	64.3	18.2	14.7	17.5	16.2

The classifiers used are of the diaphragm type, having a ½-inch space around the diaphragm to insure an even flow of pulp. The feed to the tubes averaged practically 1:1 of moisture and dry pulp.

Amalgamation is done on ten plates each 4 ft. 9 in. wide by 12 ft. long. About 28 lb. of mercury is used every morning in dressing the plates, and the loss sustained is 0.25 oz. per ton of ore crushed. The percentage of recovery by amalgamation has been as follows: 1906, 37.3; 1907, 39.1; 1908, 40.1; 1909, 40.7; 1910, 40.3 for 6 months prior to installing tube mills; and 31.0 for 3 months following installation of tubes. The reduction is ascribed to a reduced grade of ore.

The concentrate recovered on vanners averages 1.25% by weight and 15 to 18% of the gross value of the ore treated. The ratio of gold to silver in the bullion varies from 1:3 to 1:30.

The tailings from the vanners are sent to leaching tanks. Butters and Meins distributors are used, and the tanks are full of water before pulp is turned into them. The overflowing slime is treated by agitation. As the ore is variable in gold and silver content, the treatment of any tank is not decided upon until it has been sampled and assayed. The average treatment for a charge of 140 tons of ordinary grade ore is as follows: Allow to drain completely, and then give an alkaline wash of 4 tons medium solution with 200 lb. soda ash, followed by 4 tons more of medium solution and 4 tons strong solution. The displacement is then continued by adding 8 tons strong solution with 270 lb. NaCN, and repeated lots of 10 tons of strong solution until the effluent shows 1.1% total cyands (0.7% free KCN). The percolator cock is then closed and the solution circulated by a small air injector, thus keeping the solution in continuous circulation during contact. After 4 or 5 days contact the pulp is sampled and is usually shown to be ready for the next step. The solution is then drained off, displaced by 5 tons medium solution, followed by washes of from 80 to 120 tons of weak solution. The residues are then of sufficiently low grade to be sluiced to the river.

Owing to the variable silver content the strength of solution during contact has to be varied. The following examples give a good idea of the practice on rich, medium and low grade ore:

Gold.

Tons Charge.	Head.	Tail.	Ext. %
140	$21.21	$1.21	94.5
138	11.42	0.70	93.1
145	4.04	0.42	89.7

Silver.

Head.	Tail.	Ext. %.	Lb. NaCN Added.	= KCN per Ton.
10.61 oz.	1.69 oz.	84.1	320	2.65
5.50	0.61	89.1	270	2.27
2.41	0.34	85.8	130	1.04

The slime is agitated by air at 40 lb. pressure in tanks 12 ft. diameter and 30 ft. high. The solution has a strength of 0.19 to 0.35% KCN, and the time is 24 hours, after which the pulp is filtered by vacuum filters of the fixed frame type. The filter tanks are filled with pulp which is kept agitated by means of air. The solution is drawn by two wet, doube-acting vacuum pumps, maintaining a vacuum of 23 to 25 inches of mercury. The cake is allowed to build up to a thickness of ¾ to 1¼ inches in an hour. A weak solution wash is then applied for an hour and a half to two hours, after which the cake is discharged with 18 to 25% solution as moisture. Separate zinc boxes are provided for the precipitation of strong, medium and weak solutions.

The Specific Gravity Flask Used for the Measurement of Pulp.—The specific gravity flask should prove a most useful and indispensable instrument for efficient and reliable control of the conditions of mill pulp. At least this is the opinion of H. Stadler as expressed in the *Journal* of the Chem. Met. & Min. Soc. of S. Africa, November, 1911. He gives five different applications of the instrument, together with formulae.

I. Determination of Specific Gravity of Solids.—If the material is dry, a known weight in grams is placed in the flask, moistened and shaken with water to remove air bubbles, and water is added to fill the flask to the top or mark. This is weighed and the sp. gr. obtained by the use of formula 1. Wet material such as mill pulp is preferably dried and weighed after the determination of the sp. gr. of the pulp.

II. Determination of Specific Gravity of Pulp.—Almost all factors determining the nature of pulp from the millman's point of view are governed by the sp. gr. of the pulp. If the metric system is used the sp. gr. is at once obtained by dividing the net weight of the pulp by the volume occupied, or when a 1000 c.c. flask is used, by pointing off the last three figures of the net weight of the pulp in grams. The sp. gr. of slime pulp in which all solids are freely suspended may be measured by the hydrometer.

III. Determination of Percentage by Weight of Water and Dry Solid.—The usual method of determining these quantities is tedious and unsatisfactory, besides being unreliable and inaccurate. The author's suggestion is shown on formula 2.

IV. Tonnage Measurements of Total Pulp (Tp) and Dry Solids in Pulps (Ts).—The usual inconveniences of drying and weighing time samples of flowing pulps are avoided by reckoning the tonnage from the volume occupied by the total pulp (in cu. ft.) and its sp. gr., by formula 4 for the total pulp, and formula 5 for the dry solid portion only. Run the pulp into a box of known capacity, large enough to take at least one minute's run of the stream. Determine the sp. gr. from several representative samples taken simultaneously, and the calculated weight of pulp or dry slime passing during the time (t in seconds) is then used to give the hourly or daily quantities.

If, in all measurements, boxes of equal capacity are used, say 16 cu. ft. (the volume of half a ton of water) all the constant factors may be condensed into one. For a box of this capacity the formulae of Rand ore are

$$\text{Tons of total pulp in 24 hours (Tp)} = \frac{43{,}200\ p.}{t}.$$

$$\text{Tons of dry solid only (Ts)} = \frac{(p\text{-}1)\ 68609}{t}$$

Since the capacities of launders, tanks, pumps, etc., as well as the rates of overflow of classifiers are determined by the *volume* of the pulp, the fluid ton of 32 cu. ft. is frequently used as a unit. The tonnage of pulps of known sp. gr. are readily converted into fluid tons by the formulæ 7 and 9, for total pulp and dry solids respectively.

V. Relations of Flowing Quantities in Classifiers.—The relation of flowing quantities in classifiers may be calculated from the percentage of any of their components measured at the inflow, overflow and underflow. No component can be measured so quickly as the percentage of dry solid taken with the sp. gr. flask. From the percentages of dry solid so obtained the tonnage of total pulp underflow (as a percentage of the total pulp inflow) is calculated from formula 10, and the tonnage of dry solid underflow (as a percentage of dry solid inflow) by formula 11. All the formulae are based on the sp. gr. of pure water, but they are applicable to ordinary cyanid solutions with enough accuracy for practical purposes, except in the case of thin pulps, such as turbid water, overflow of classifying tanks, etc. The author states that the sp. gr. of ordinary cyanid solutions assaying 0.126% KCN and 0.01% alkalinity has been determined to be 1.0021, and this small variation from pure water is almost negligible.

Formulae.—The values of the different terms in the formulae are as follows

v = content of flask in c.c.
w = net weight of (v) c.c. pulp in grams
p = sp. gr. of pulp (mixture of solid and water).
d = sp. gr. of solid.
Tp = tons of pulp (water and solid).
Ts = tons of dry solid in the pulp.
W = % by weight of moisture in pulp.
S = % by weight of dry solid.
V = volume of pulp in cu. ft.

k = a constant for any particular value of $d = \frac{100\,d}{d-1}$.

Fl = fluid tons (1 Fl = 32 cu. ft. pulp).

I. Determination of density (d) of material (a) in grams.

(1) $d = \frac{a}{v + a - w}$.

II. Relation between sp. gr. (p) and net weight of pulp (w).

(2) $p = \frac{w}{v}$, $w = v\,p$.

III. Relation between % of dry solid (S) and moisture (W), and sp. gr. of pulp (p). W S 100%.

(3) $S = \frac{(p-1)\,k}{p}$, $p = \frac{k}{k - S}$.

IV. Tonnage measurements of pulps (Tp) and dry solid in pulps (Ts).

(4) Tp = .03125 Vp.

$$Ts = V\,(p-1)\,\frac{k}{3200}$$

(5) Ts = V (p—1) .04063

Tonnages and fluid tons.

(6) Tp = Fl. p.

(7) $Fl = \frac{Tp}{p}$

$$Ts = Fl\,(p-1)\,\frac{k}{100}$$

or when

$$\frac{k}{100} = 1.588 \text{ (Rand ore)}$$

then

(8) Ts = Fl (p — 1) 1.588

or

(9) $Fl = \frac{Ts}{(p-1)\,1.5882}$

V. Relations of flowing quantities in classifiers

Inflow (i)

Wi = % water
Si = % dry solid } pi sp gr of inflow
Ip = % tons pulp inflow (100%)
Is = % tons dry solid inflow (100%)

Overflow (o)

Wo = % water
So = % dry solid } po sp gr
Op = tons pulp overflow
Os = tons dry solid overflow (in % of inflow)

Underflow (u)

Wu = % water
Su = % dry solid } pu sp gr
Up = tons pulp underflow
Us = tons dry solid underflow (in % of inflow)

$$\text{Circulation} = \text{Circulation factor} = \frac{\text{pulp (Tp)}}{\text{dry solid (Ts)}} \text{ of underflow}$$

$$\text{Circulation} = \frac{100\,(S - So)}{Su - So}$$

$$\text{Circulation} = \frac{100\,Si\,(Su - So)}{Su - Si\,(Su - So)}$$

(11) $Us = \frac{Si\,(Su - So)}{100\,(Su - So) - Si\,(Su - So)}$

(12) $Up = \frac{pu}{pu - 1} \cdot \frac{100\,(pu - po)}{pi - po}$

$$\text{Circulation} = \frac{pu}{pu - 1} \cdot \frac{po\,(pi - 1)}{pi - po}$$

(13) $Us = \frac{pu}{pu - 1} \cdot \frac{po\,(pi - 1)}{pi - po}$

Slow-Speed Chilian Mills.—In a paper published by the Mexican Institute of Mining and Metallurgy Mr. J. B. Empson presents many arguments in favor of the slow-speed Chilian mill as a fine grinder. His work supplements very admirably that of Mr. D. C. Bayldon, who presented similar matter before the Institute of Mining and Metallurgy (London), and which was reviewed in our issue for February, 1911.

Mr. Empson is of the opinion that engineers generally do not appreciate the good qualities of this mill as a fine grinder, and that they follow too closely in the path of custom which dictates the use of other grinders. We quote from Mr. Empson:

"The types with which the writer is familiar are extremely crude both as regards the method by which the power is applied, as well as the impossibility of preventing the grit entering the bushing in which the trunnion shaft turns, hence causing an altogether needless expense in the upkeep. The mills in use at La Union in Pachuca, and at El Bote, Zacatecas, are of a different type to those above mentioned and are far superior in every respect. The main reason, I understand, why these latter types of mills have not come into more general favor is that of first cost, which, if my information is correct, would appear excessive; probably owing to their great weight, the question of freight and duties plays an important part.

"There are several claims to be made in favor of the Chilian mill in Mexico as compared with stamps, especially in small installations.

"People who argue in favor of stamps base their claims on the following or similar points: simplicity, ease with which repairs can be made, small space occupied, operation in units, availability of men who are familiar with their operation. Much can be written in favor of stamps, especially as applied to ores which do not call for reduction to slime, but on which leaching of sand is possible; under these conditions, where ore is to be crushed to ¼ in. mesh in stamps and reduced to 30 or 40 mesh in tube mills, the slow speed Chilian does not compete. The slow speed Chilian is essentially a fine grinder and as such can show a mechanical efficiency that cannot be obtained by stamps and tube mills. Hence its application to Mexican conditions, where the latest metallurgical practice is to grind silver ore so that all will pass 100 mesh and in some mills so that not more than 20 per cent will remain on a 200 mesh screen. To do this work with stamps entails the installation of one tube mill to each 5 stamps when each stamp weighs 1250 pounds and putting these at their maximum capacity of 10 tons per stamp according to Mexican practice gives results as follows:

"10 stamps. 1250 lbs. each. 100 drops per min = 27 h.p. or 2.7 per stamp 100 tons deducting 10 tons for slime in batteries = 90 tons, divided between two tube mills gives a charge of 45 tons per mill. Then allowing two 5 x 16 ft. mills to do this work the rated running power required for each mill would be 46 hp., totalling 92 hp.

"Therefore 27 hp. plus 92 = 119 hp. or 1.19 per ton.

"Tube mills require approximately 1 hp. for every ton ground to 200 mesh.

"To do the same work with slow speed Chilian mills would require an installation of:

"Four Chilian mills of similar design to those in use at S. Luis de la Paz requiring 15 hp. each and crushing approximately 100 tons or 25 tons per mill per 24 hours to an estimated degree of fineness as per figures published by Mr. Megraw on work done at the Sta. Elena mill at San Luis de la Paz.

On 60 mesh	1.15 per cent
Through 60 on 80 mesh	5.65 per cent
Through 80 on 100 mesh	0.15 per cent
Through 100 on 200 mesh	25.75 per cent
Through 200 mesh on	67.30 per cent

"Considering these figures it is seen that 34.70 per cent is the amount that will not pass a 200 mesh screen, and of this amount 25.75 per cent passes the 100 mesh screen and remains on 200 mesh, leaving the small percentage of 6.95 as staying on 100 mesh. It is to be regretted that no 150 mesh screen was used in this screen classification. This is stated to be an average result. Hence it is seen that in crushing 100 tons of ore by this method the amount to be reground is 34.75 tons, of which only 6.95 tons can be classified as being coarse. To do this work would take a 4 x 16 ft. tube mill using 27 hp. at rated running, making a total of 87 hp. for the whole installation, equivalent to 0.87 per ton of ore crushed to 200 mesh. Naturally the finer the product given to the tube mill to crush the greater will be the output of the mill. From experience gained from an installation of this kind it has been shown that the difficulty is to give the tube mill enough work to do in order to allow it to work efficiently. From the figures as given above it will be seen that with the Chilian mill installation there is a saving of 0.32 hp. per ton as compared with stamps and tube mills.

"Some extremely interesting comparisons have been made recently by writers in the technical mining journals as to the merits of stamps and tube mills as compared with slow speed Chilian mills.

"I would refer members interested to read with special attention the article by Mr. W. H. Urbiter published in the *Engineering and Mining Journal* of August 5, 1911.

"Mr. Urbiter in reviewing the situation gives figures as follows:

Sta. Elena S. Luis de la Paz.

2 roller-type slow speed Chilian mills.

	Tons per hp. Day.	Relative Mechanical Efficiency.
67.3 per cent through 200....	1.84	49.09 per cent
Hacienda La Union. Pachuca.		
Same as above.		
80 per cent through 200 mesh.	1.70	46.13 per cent
South Africa. Heavy Stamps.		
Tube Mills.		
90 per cent through 90 mesh..	1.53	40.48 per cent

"Putting the South African practice on a par with Mexican practice, it would appear that if the South African mills were crushing to the same fineness as those in Mexico the relative mechanical efficiency would be much lower.

"American practice of 3 roller fast running type of Chilian mill:

39.4 per cent through 200 mesh.	2.35	55.73 per cent

"Owing to the relatively small amount remaining on 200 mesh, it will be seen that this class of mill, when crushing to the same degree of fineness as the mills in Mexico, would lose to a large extent their relatively high mechanical efficiency.

"From the above figures it will be seen that when the fineness of the final pulp is taken into consideration, it is evident that the slow speed Chilian mill is a much more efficient machine to reduce ore to the required fineness as demanded by Mexican practice than any of the other combinations.

"Itemized costs per ton of ore ground, as published by Mr. Megraw on actual work done at the Sta. Elena Mill, are as follows:

	Cents.
Labor	0.03
Lubrication	0.01
Power	0.288
Tyres and Dies	0.129
Extra repairs	0.010
Total	0.467

"Sr. Narvaez of the Hacienda La Union in Pachuca gives a cost of 0.558 cents Mexican for reducing ore so that 80 per cent will pass a 200 mesh screen.

"At the Sta. Elena mill the ore is crushed so that 67.3 per cent passes 200 mesh.

"Against this the cost of grinding a ton of ore to approximately the same fineness by the use of stamps and tube mills will range from 65 cents to over a peso per ton, according to the size of the mill and nature of power used.

	Stamps.	Tubes.	Total.
Goldfield Consolidated give	0.42	0.40	0.82
Tonopah Belmont	0.42	0.34	0.76
Minas del Tajo, Sinaloa	...	...	0.96

Pachuca Mills, Approximate average, 80 to 90 cents Mex. cy.

"In these figures there is no allowance made for depreciation of mills either in Chilian mills or stamps; nor is there any allowance made for crusher power, this being the same in either case.

"When one is confronted with figures such as these it must be evident to the most casual observer that either there must be great scope for improvement in the stamps and tube mill work as at present carried out, or that through ignorance and prejudice the slow speed Chilian mill has not received the attention that apparently it deserves at the hands of engineers. On considering the matter I believe that it will be generally admitted that in the majority of cases the stamp and tube mill work as carried out in Mexico in large installations is on the whole excellent, hence we have no other excuse than to say that we as engineers have failed to credit the slow speed Chilian with the numerous advantages that, as far as I can learn, it is entitled to.

"The Chilian mills, with the exception of a few installations (the managers of which, by the way, are enthusiastic supporters of this type of mill), are as a rule a very crude type, which years ago may have given satisfaction, but now that in most cases electric power is available, and that the mechanical feeder has been perfected, and other essential adjustments, e. g., the Mantey offset and modern methods of transmission have come into general use, it does not appear reasonable that the slow speed Chilian should be condemned by those who persist in using this out-of-date type.

"The following are some of the apparent benefits to be gained by the use of Chilian mills as compared with stamps:

"Less height required. Cheaper foundations. Fewer repair parts required. Ability to withstand the roughest handling. Breakdowns and hence delays will be found less than with stamps. Over-feeding or under-feeding does not hurt the mill. In some cases absence of all screens. Absolutely unskilled labor can operate it. Attendance if mechanical feeders are used is very small. Repairs to nearly every part can be made on the ground. Minimum vibration and hence minimum depreciation of mill.

"Steel wearing parts will last from 18 months to 2 years.

"Doubtless there are other points which could be mentioned, but I think that with the above sufficient has been said to show that more attention should be paid in the future to this type of mill."

Mr. Empson has designed a mill embodying the advantages

described by Mr. Bayldon, and drawn from his own experience. He has endeavored to introduce: Improvements in the method of applying power; complete change in the form of the pan; trunnion shaft turning in a center bearing and not in the boss of the muller, where it is subjected to grit; device for allowing the mullers to lift independently over any unbreakable object; improved method of feeding ore; more discharge area which can be used either with the overflow method or with screens. The Mantey offset also has been embodied. In this the axle of the wheel is set behind a diameter line to which it is parallel, so that in the turning of the mill the roller, not being true with the die, is more or less shoved over it, while at the same time it revolves. When the offset is properly proportioned to the speed at which the mill runs it is perfectly successful, but as the resistance is that of grinding, it has the objection of consumption of power and metal common to grinders, in the ratio of this action.

The estimated capacity of the proposed mill is 40 tons in 24 hours, requiring 17 to 18 hp. It will require only 5 hp. to reduce a ton of ore to practically 100 mesh.

Cupels and Cupellation.—In an effort to ascertain some of the factors affecting the cupellation of silver-lead buttons obtained in assaying, R. C. Benner and M. L. Hartmann have made a series of experiments which they have published in the *Mexican Mining Journal* of March, 1912.

The authors quote the earlier work of J. Eager and W. Welsh to show the effect of temperature, quantity of lead and quantity of silver on the cupel loss. The following tables embody these results:

Temperature Variable; Lead and Silver Constant. 200 mg. Silver and 10 g. Lead.

Temp. Deg. C.	Silver Loss, per Cent.	Remarks.
700	1.02	Feathers
775	1.28	Feathers
850	1.73	No Feathers
925	3.65	No Feathers
1000	4.87	No Feathers

Temperature 685 Deg. C; Silver, 200 to 205 g.; Lead Variable.

Lead, Grams.	Silver Loss, per Cent.
10	1.30
15	1.38
20	1.52
25	1.85

Temperature 750 Deg. C; Lead, 15 grams; Silver Variable.

Silver Mgs.	Silver Loss, per Cent.
2	4.40
5	2.63
20	2.34
50	2.46
100	2.40
200	1.64

In the matter of specifications for cupels the authors state that no uniform conditions can be laid down on account of variations in materials and the climate of the place where the cupels are made and used. They made experiments with different mixtures to see whether suitable substitutes for boneash could be found. The experiments were made in an electrically heated muffle, and the temperatures were determined with a Le Chatelier platinum-iridium pyrometer. When thoroughly dry the cupels were heated in the muffle to about 800 degrees C. The lead button was then dropped in, and the muffle door closed until the buttons had opened and begun to oxidize. The cupels were then pulled to the front of the muffle where the temperature was about 665 degrees C. When the buttons had become quite small the cupels were pushed back into the muffle, where the temperature was from 750 to 800 degrees C.

Boneash and several other materials were tested to ascertain the silver losses, the results being summarized as follows:

Uniform Heat Conditions; 10 grams lead, 40 mg. silver.

Cupel.	Silver Loss, per Cent.
Morganite	1.97
Casseite	3.09
Brownite	2.89
Boneash	2.36
Portland cement	3.38
Boneash and cement (equal parts)	2.95

It was further determined that cupels made of different grades and sizes of boneash gave the same percentage loss of silver within the limits of experimental error.

Lead.

Blast-Roasting of Galena.—The early theories of the chemistry of blast-roasting of galena have been revised from time to time until some of the first proposals are now recognized as entirely erroneous. A very lengthy paper on the subject was presented to the Institution of Mining and Metallurgy (London) by Mr. C. O. Bannister, and published in the February *Bulletin* of that organization.

Mr. Bannister reviews at some length the various theories of the inventors, discussing their patent claims, and giving the discussion which other writers have presented on the same subject. He then gives the detailed results of a long series of experiments on the different forms of blast-roasting, and comes to certain conclusions which alone can be presented here.

1. The older theories relating to the formation and subsequent reaction of peroxides, plumbites and plumbates are wrong; when these compounds are formed it is only in minute quantity, quite insufficient to affect the final results. The former theories depending on definite reactions between calcium sulphate and lead sulphide also are wrong.

2. Later theories depending merely on the diluent effect of the various agents added are only partly true, as important chemical reactions take place in the presence of lime, limestone and magnesia.

3. The oxidation of lead sulphide takes place in three stages, (a) its partial oxidation to a mixture of sulphate and oxide; (b) a reaction between the sulphide and sulphate; (c) a reaction between sulphide and oxide.

4. In the presence of lime, limestone or magnesia, the sulphates of calcium or magnesium are formed in preference to sulphate of lead, leaving a much larger quantity of lead as oxide in the roasted material.

5. Silica and calcium sulphate act merely as diluents, taking no chemical part in the reactions until a temperature of over 1000 degrees is reached.

6. Ferric oxide in certain physical states appears to act as a catalyzing agent, lowering the temperature of oxidation of lead sulphide and increasing the amount of lead sulphate formed during the roast.

7. Silica acts at high temperatures, 1000 degrees and above, in decomposing lead sulphate and calcium sulphate, the latter being thus decomposed whether it be added as such or formed during the preliminary stages of the roast.

International to Build Lead Refinery.

General Manager E. P. Mathewson, of the International Smelting & Refining Company, which has a copper and lead smelter at Tooele, Utah, is authority for the statement that the company has decided to build a new lead refinery at East Chicago.

A tract of land has been purchased and plans for the plant have been completed. It is estimated that the plant should be ready for operation in about six months.

Recent Metallurgical and Chemical Patents.

Iron and Steel.

Balling Scrap Iron.—The balling of scrap iron is a preliminary step for raising scrap to a welding temperature, and roughly welding or agglomerating it into a single mass which can then be squeezed and rolled into a homogeneous body of iron. Mr. DAVID H. LENTZ, of Chicago, Ill., has patented a mechanical device for accomplishing this object. The machine is shown in elevation and plan in Fig. 1. It consists of a fire

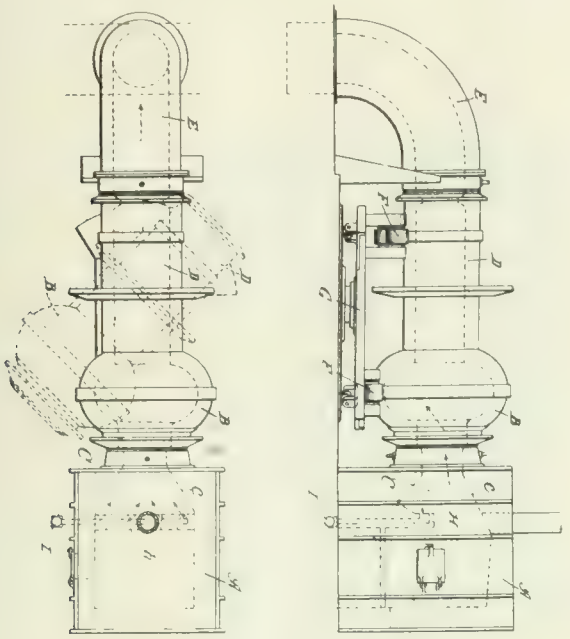

FIG. 1.—BALLING SCRAP IRON.

box *A* connecting with the balling chamber *B* and preheating chamber *D*. *B* and *D* are one member, and are adapted to be rotated on a turntable *G* into a position shown in the plan. The flue *E* is simply a down flue to carry off the gases of combustion from the furnace *A*.

In operation the furnace is first heated to a high degree of temperature in order that its refractory lining may be hot when the operation begins. The movable chamber is then swung into the position shown in the plan, and the charge of scrap iron is placed in the open end of *D*. The chamber is then swung back into operating position and revolved by any suitable means, not shown. The scrap tends to spread out over the surface of *D*, where it is subjected to preheating by the flaming gases coming from the fire box. The inclination of the preheating chamber is such that pieces of scrap are caused to move toward the balling chamber *B*; and the operation is conducted in such a manner that by the time all the pieces of scrap have reached the balling chamber they are at a welding heat. The speed of rotation may then be increased, and the mass welded into a homogeneous ball of metal ready for squeezing and rolling. Thereupon the revolving member is again swung out of operating position, the ball removed and a new charge inserted. The inventor states that he has operated such a furnace for eight hours continuously, and has welded a charge of 500 lb. of scrap in practically seven minutes. He further states that the furnace can be operated so as to weld such a charge once every ten minutes. The inventor is of the opinion that his apparatus gives results superior to those obtained by other common methods of agglomerating, in which manual labor is used, giving uncertain and irregular results. (11,012,871, Dec. 26, 1911.)

Enriching Furnace Blast with Oxygen.—In a patent granted to Mr. CHARLES F. JENKINS, of Washington, D. C., the inventor gives specifications for his method of using barium oxide as a means of securing oxygen gas with which to enrich furnace blast. It is well known that barium oxide may be peroxidized and then made to yield the extra atom of oxygen taken on. This is the principle of which Mr. Jenkins takes advantage.

Fig. 2 shows a sketch of the application to a blast furnace.

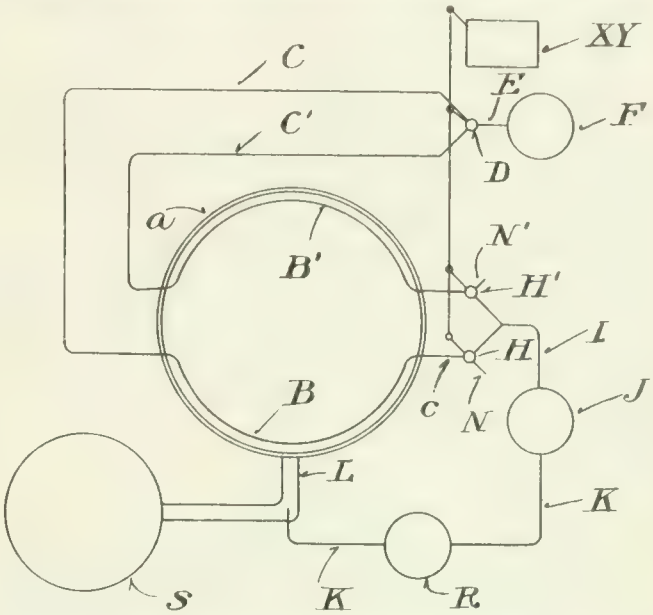

FIG. 2.—ENRICHING BLAST WITH OXYGEN.

The furnace is represented at *a*. *B* and *B'* are two receptacles for barium oxide, and are placed so that the hot gases from the furnace will surround them. In Fig. 3, we see an arrangement in which the oxide chambers are arranged in vertical twin sections in a heating chamber outside the furnace. Referring again to Fig. 2, the operation of the apparatus is as follows: The oxide receptacles *B* and *B'* being charged with barium oxide, the pump *F* is started which drives air through the pipe *E*, the valve *D* and the pipe *C* into the receptacle *B*, where the barium oxide takes up oxygen, forming barium

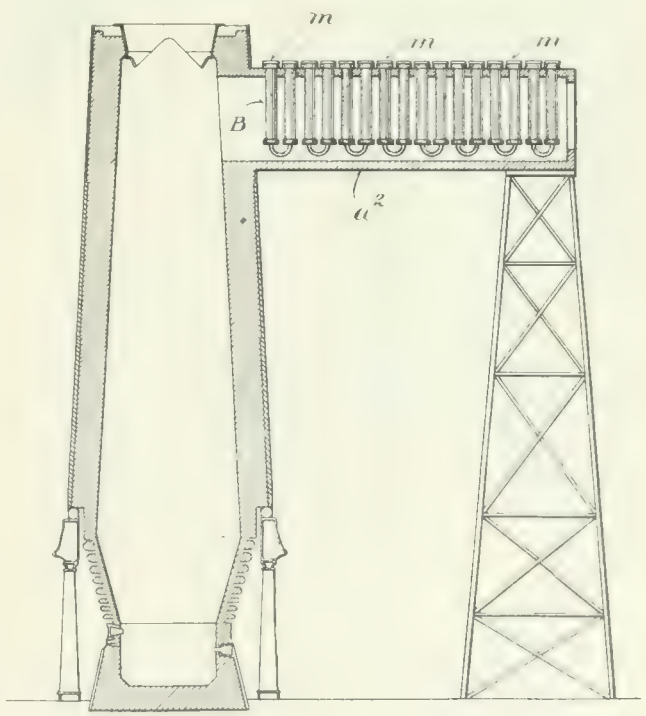

FIG. 3.—FURNACE WITH ATTACHMENT FOR ENRICHING BLAST.

peroxide. The nitrogen passes on through pipe *C* and valve *H*, escaping from pipe *N*, unless it is desired to employ the nitrogen for some useful purpose. At the expiration of, say, 10 minutes, the three-way valves *D*, *H* and *H'* are thrown over, which closes the pipe *C* and directs the flow of air through *C'* into *B'*, where it oxidizes the barium charge and escapes through *N'*. The suction pump *J* having been started, a partial vacuum is created in the receptacle *B* and the peroxide gives up its oxygen which is drawn off through the pump *J*, the equalizing chamber *R* and the pipe *K*, to be mixed with the air blast *L*, the latter being supplied by the pump *S*. The valves are shifted every 10 minutes, and as the pumps do not stop the supply of oxygen is continuous. Any suitable means may be adopted to regulate the heat coming in contact with the oxide receptacles. (1,010,265, Nov. 28, 1911.)

Slag Pocket for Open Hearth Furnaces.—In the usual operation of an open hearth furnace, the accumulation of slag in the slag pockets is the cause for loss of much time in cleaning said pockets. In order to obviate the ordinary difficulties and losses attendant on this operation, Mr. Thomas S. Blair, Jr., has designed a removable slag pocket which is an integral structure in itself, adapted to be attached to and detached from an open-hearth furnace. In Fig. 4 is seen a

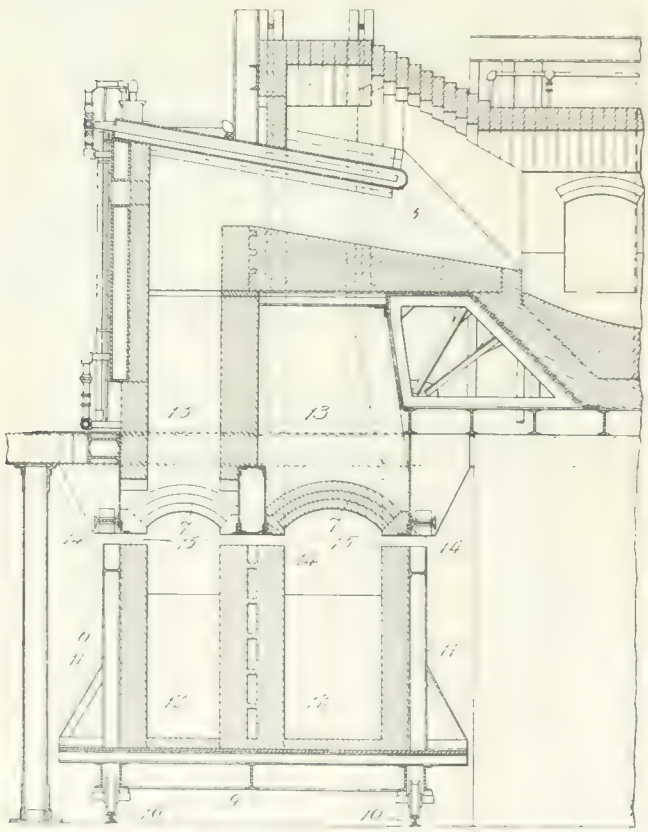

FIG. 4.—MOVABLE SLAG POCKET FOR OPEN-HEARTH FURNACE.

drawing of one end of a furnace provided with the patented slag pocket.

The slag pocket 6 is complete in itself, separate from the remainder of the furnace, except the slag pocket arches 7 and their means of support. The movable pocket consists of a wheeled carriage 9, having metal posts 11 suitably braced to provide a framework for the brick walls forming the pockets 12. The dimensions of the structure are such as to adapt it to fit under the down-takes, registering its pockets therewith. On placing a slag pocket in position there are narrow spaces at the top 15 and at the end, not shown, which are temporarily filled with brick, thus forming a tight joint between the pocket and the furnace. When it is desired to remove the pocket the bricks are knocked in and the pocket is wheeled out of position and another moved in. Thus only a few hours' time is required to accomplish what in ordinary practice would require several days. (1,012,236, Dec. 19, 1911.)

Miscellaneous.

Magnetic Removal of Dust from Roaster Gases.—In roasting ores containing sulphide of iron the material is largely converted into magnetic forms of iron. Dust particles carried off by the roaster gases are thus magnetic and may be removed by the application of a magnet. This is the basis of a patent recently granted to Utley Wedge, of Ardmore, Pa., for means of purifying roaster gases by eliminating fine solid particles which may be detrimental to the subsequent application of the gas. The customary high temperature of the furnace gases is not high enough to destroy the effectiveness of the magnets, but on the contrary the efficiency of a steel magnet may be increased thereby. (1,012,488, Dec. 12, 1911.)

Fused Silica Ware, its Manufacture, Properties and Uses in the Chemical Industries*

By A. L. Marsh.

The production of fused silica apparatus in sizes suitable for manufacturing operations was made possible by the Thermal Syndicate's electric-furnace process, which was patented in 1904. Prior to that date small transparent articles had been made by various experimental workers from rock crystal.

The method generally adopted was to build up the article from small pieces of crystal in an oxyhydrogen blow-pipe flame. The size of these vessels was, of course, limited, but despite this and their necessarily high cost, they were used for purposes where the peculiar properties of the ware rendered it more serviceable than other materials.

The electric-furnace process of fusing pure silica is, of course, applicable to the manufacture of large and small apparatus, the maximum sizes being pipes of 12 in. diameter and 30 in. long, basins 20 in. diameter, and retorts of 75 litres capacity. The articles made by this process are not transparent like the rock crystal product, as the mass does not become perfectly fluid during fusion, but only attains a plastic consistency with the result that the small air bubbles disseminated through it, are unable to rise to the surface.

The small ware intended for laboratory purposes is subjected to a special process which increases the transparency and gives the material a highly glazed surface. The glaze is of the same composition as the ware, that is to say, it is pure silica and is not an added alkaline glaze. The application of the glazing process is at present limited to ware not exceeding 6 in. in diameter.

Fused silica possesses properties which render it of great value in the chemical allied industries, the principal one being its great resistance to heat and to acids. It is highly refractory, the melting point (which is not well defined) being between 1700 deg. C. and 1800 deg. C. The material softens appreciably at lower temperatures (about 1500 deg. C.), but does not readily lose its shape.

There is one point in connection with fused silica that is sometimes overlooked and that is its tendency to devitrify or to pass from the vitreous to the crystalline state, if it is continuously heated above 1200 deg. C. This, of course, does not prevent the use of the material for intermittent work at temperatures considerably greater than 1200 deg. C.

The heat resisting properties of the ware received an unsolicited testimonial when the British section of the Brussels Exhibition was destroyed by fire in August, 1910. The metal fittings of the stand were fused into a shapeless mass, but the various pieces of fused silica remained intact despite the enormous temperature attained. The certificate received from the

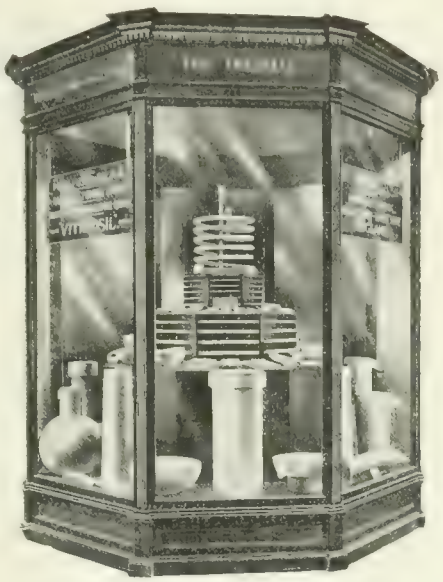
* Paper read before the New York Section of the American Chemical Society on March 8.

Works Department of the British Commission reads as follows: "Showcase completely destroyed, but the contents have resisted the fire. The damage to the exhibits has been caused only by the structure and iron girders falling across them."

The ware is unaffected by acids, with the exception of hydrofluoric and phosphoric acids. In the latter case the action only becomes pronounced at 400 deg. C., so that for practical purposes such as the concentration of phosphoric acid, it can be considered as being proof against this acid.

The electrical insulating value of fused silica is high, and the resistivity decreases very slowly with a rise in temperature. This suggests that the ware may be utilized for insulating purposes when the required shapes can be produced.

There are various types of electrical heaters or radiators in use in England and in Continental Europe, consisting of a heating element of non-oxidisable wire enclosed in thin walled tubes of fused silica. The tubes allow the glow of the spiral to be seen, and a very pleasing effect is produced.



APPARATUS MADE FROM FUSED SILICA

In the chemical industry, fused silica has found extensive applications, particularly in the construction of sulphuric, nitric, and hydrochloric acid plants. Certain operations such as the concentration or distillation of sulphuric acid have always presented difficulties to the manufacturer by reason of the failure of the material from which the plant has been built. In some cases, costly vessels of platinum or platinum-iridium have been used to overcome the difficulties.

Fused silica has been adopted with great success for these two operations, some forty basin-type concentrators being in daily use in England alone. The silica basins are invariably exposed direct to the fire gases so that low fuel consumption and high outputs are obtainable.

There are, of course, many special applications in the sulphuric acid industry besides concentrators, but these will readily suggest themselves to the acid manufacturer.

In the case of nitric and hydrochloric acids, fused silica pipes have been extensively applied in place of earthenware. The pipes are made in the usual shapes with either socket or tapered joints. Considerable care is necessary in making the joints, owing to ordinary jointing materials and cements having coefficients of expansion considerably greater than silica. The best form of joint is one relying on asbestos for the main portion of the joint, the outside only being finished with cement.

Italian asbestos must always be used, as the Canadian variety swells considerably when brought in contact with strong acids.

A large variety of special shapes of apparatus, such as coils, tanks, retorts, crucibles, etc., are made for various branches of the chemical industry where either resistance to acids or heat, or a combination of these properties is desired.

It is interesting to note that ware of an ornamental character, such as finger bowls, fruit plates, etc., having a highly lustrous surface can be made by the same process as the chemical ware. The lustre is due to the reflection of light from the surfaces of highly distended air bubbles, and it is therefore untarnishable.

The Use of Lactic Acid for Cleansing Filtering Mediums.

The new cyanide plant at the Ajax mine, in Victor, Colorado, has attracted general attention as the pioneer plant of the Clancy cyanamide process.

However, another important novelty has also been introduced there quietly into commercial practice in connection with the filtration plant, and it should be stated at once that it has resulted in complete commercial success. This is the use of lactic acid instead of hydrochloric acid for cleansing the filters.

In the past the general practice when calcium compound deposits impeded the efficiency of filtering mediums has been to dissolve them out by a dilute solution of hydrochloric acid. However, the use of hydrochloric acid has some disadvantages. The fibres of the filtering medium are rendered hard and stiff, and are completely destroyed in time. Troubles in handling the acid, high transportation charges, freight, dues on return of empties, breakages, etc., also the fact that the commercial acid of 20 degrees Beaume contains less than a third of true hydrochloric acid, make the final cost excessive. Nor has any practical method been brought forward whereby this acid, after being used, can be regenerated economically. Finally, sulphuric acid, which forms calcium sulphate on the filtering mediums, and in time causes them to become useless, is always present in commercial hydrochloric acid.

The use of lactic acid in the operation of cleansing filtering mediums is a distinct and important advance for this purpose, entirely eliminating as it does the imperfections and disadvantages just enumerated.

The incrustations of calcium compounds are not only dissolved by lactic acid as efficiently as by hydrochloric acid, but the fibres of the filtering medium, instead of being rendered hard and stiff, and finally destroyed, as is the case with hydrochloric acid, are rendered soft and pliable, therefore more efficient and of longer endurance when lactic acid is used.

Lactic acid being non-volatile and non-corrosive, is safely handled without the precautions that are necessary with hydrochloric acid. Lactic acid is transported in barrels, etc., at ordinary freight rates, instead of the high rate charged for hydrochloric acid. Lactic acid costs at the factory slightly more than hydrochloric acid, but this is more than offset by lower transportation charges and no return freight on empty acid carboys.

Lactic acid contains no sulphuric acid, therefore no incrustation of calcium sulphate is formed in the filtering mediums, as is the case with hydrochloric acid. As the efficiency of the filtering mediums is always maintained high and their life is lengthened, the cost of filtration is also reduced.

Finally, lactic acid can be regenerated for re-use from calcium lactate economically and practically. This means the elimination of delays in the delivery of fresh acid, and a partial elimination of the cost of fresh acid, since when once the bath of lactic acid has been made the only fresh acid required is for the replacement of the small amount which is lost through mechanical losses.

A 10 per cent solution of lactic acid, at a temperature of 150° Fahr., gives excellent results, as a solvent for calcium compounds from filtering mediums.

The regeneration of the lactic acid is accomplished in the following simple and efficient manner:

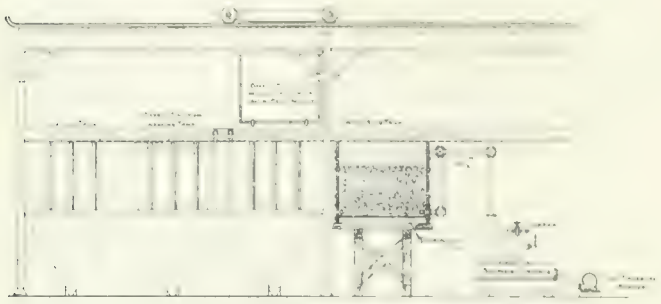
The mechanical devices required to effect the regeneration are simple in construction and operation, as is seen from the accompanying sketch in which the apparatus is shown in conjunction with a Moore filter system in cyaniding.

The apparaus required consists of a sulphur-burning furnace, an air blower, and the necessary piping, the latter being fitted up so as to connect the furnace with the perforated pipe placed at the bottom of the acid treatment tank.

The regeneration is accomplished as follows: The furnace is charged with ordinary sulphur, the latter ignited, and the

sulphur fumes forced through the calcium lactate solution, by means of the air blower, until all of the calcium has been precipitated, while the lactic acid is thereby regenerated, after which the sulphur furnace is extinguished and the operation stops.

The calcium precipitate is usually allowed to accumulate in the acid tank until sufficient has been accumulated to form a



APPARATUS FOR REGENERATION OF LACTIC ACID.

good cake on a basket of leaves when it is extracted, washed and dumped.

In practice it is found that three pounds of lactic acid are regenerated with a consumption of less than one and one-quarter pounds of ordinary sulphur.

Thus by substituting lactic acid for hydrochloric acid as a solvent for calcium compounds from filtering mediums, and by regenerating the lactic acid by means of sulphur, the cost of maintaining and cleansing the filtering mediums is greatly decreased and the efficiency of the same can be maintained at their maximum. Further, the costly and dangerous transport of hydrochloric acid is replaced by the cheap and simple one of sulphur in its place.

At the Ajax mine it has been found very convenient to remove a single leaf of the filter whenever this becomes necessary and give it a simple scrubbing with a 1 per cent solution of lactic acid at ordinary temperature, and then replace the leaf again in the basket. In view of the small amount of lactic acid used and the low freight rates to Victor, regeneration of the lactic acid is not practised at the Ajax mine.

The question whether regeneration is advisable or not depends on local conditions. In places remote from centers of supply regenerations of the lactic acid would certainly prove very convenient and economical.

The patents for this process are owned by the Moore Filter Company of New York City.

Double Reflecting Galvanometer for Taking Recalescence Points.

By A. Schramm, E. E.

The determination of recalescence points—now so well known through the more and more extended use of metallographic methods—is generally based upon the principle that chemical and physical changes within a substance are in general accompanied by an evolution or absorption of heat.

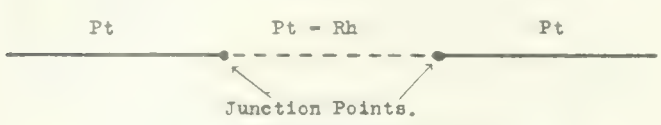


FIG. 1.—DIFFERENTIAL THERMOCOUPLE.

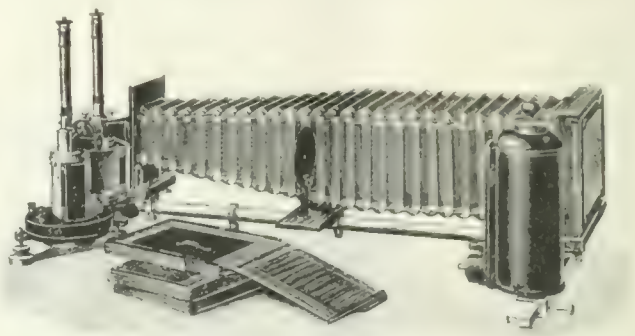
In this article the differential method will be considered only, and after a short discussion of the same, a detailed description of the double reflecting galvanometer will follow.

The principle of this method is to measure the temperature differences between a neutral body and the metal. This neutral body must consist of a material which is not subjected to internal changes when heated or cooled. Platinum, porcelain or, when the temperatures are very low, even nickel, etc., serve this purpose best. It is also desirable that the neutral body has, as near as possible, the same emissivity and heat capacity as the steel to be tested. The temperature differences are measured by means of a differential thermo-couple, which consists of two platinum wires and one platinum-rhodium wire welded together, as shown in Fig. 1. When the two junction points of this element are at the same temperature, they develop the same e.m.f., but as they are connected in opposition, no flow of current can be produced.

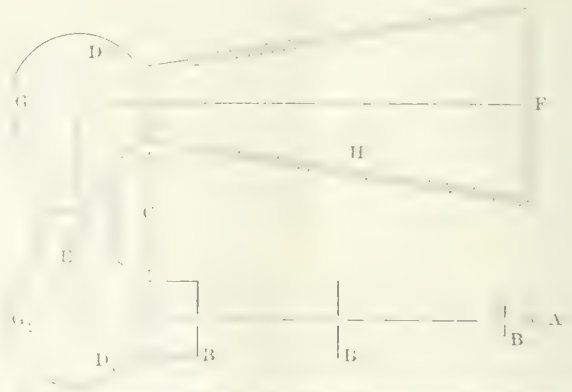
The double reflecting galvanometer (Fig. 2), consists of



three distinct parts: the two galvanometers, the source of light, and a photographic camera for drawing the curves. The arrangement of these three parts is shown in Fig. 3.

A ray of light emanating from the source of light A falls through the lenses C and the diaphragms B on the mirror D_1 of the first galvanometer. After striking this mirror, its horizontal movement is changed into a vertical one by the reversing prism E. From there the light is reflected on the mirror D_2 of the second galvanometer, where its movement is again transformed into a horizontal one. Both movements result in a curve on the focusing screen F of the camera H.

Fig. 2 represents the complete outfit. The apparatus is pro-



vided at the lantern with two diaphragms, a larger one for observation, and a smaller one for taking curves photographically. The lenses, diaphragms, and the light tight mountings of the reversing prism prevent side lights to penetrate into the camera. It is, therefore, by no means necessary to put this machine into a dark room when taking the curves with photographic plates. When removing the plate holders or adjusting the camera as well as the lantern, jarring can not be transmitted over the light tight connection between the galvanometer G_2 and the camera, owing to the absence of any mechanical connections between these parts.

When taking curves, the neutral body and the piece of iron to be tested, have to be placed into a suitable furnace so near each other that they always have the same temperature. One

junction point of the differential thermo-couple is placed into the neutral body, and the other one into the test piece. The two free ends of this element are then connected with galvanometer G_1. By means of a regular thermo-couple the temperature of the test piece is determined and measured by galvanometer G_2.

Fig. 4 shows a curve, which was taken with a double reflecting galvanometer of the kind described above. The abscissæ

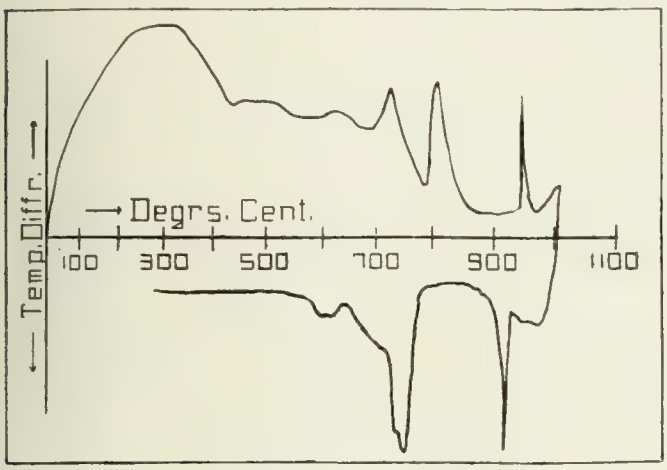


FIG. 4.—CURVE TAKEN WITH DOUBLE REFLECTING GALVANOMETER.

represent the temperature differences between the neutral body and the test piece, and the ordinates the temperature of the test piece itself. As the emissivities of both bodies were not alike, the curve does not follow the zero line, especially at the lower temperatures; nevertheless the curve shows the recalescence points very clearly, as can be noted on the one at 950 deg. C., and it can be seen also that when cooling, the recalescence point occurred nearly at the same temperature, viz.: at at 920 deg. C.

This experiment was performed in 1½ hours, which is much shorter than any of the older ways. When the instruments are set properly, the only attendance needed is the regulation of the furnace, which can be done by any unskilled workman.

A Very Simple Electrical Method for Testing Water.

"The Digby and Biggs Dionic Water Tester" is the title of a very interesting pamphlet by Mr. S. Evershed (of Evershed & Vignoles, Ltd., Chiswick, W., London), sent to us by Mr. James G. Biddle of Philadelphia, Pa. The fundamental idea is to substitute a measurement of electric conductivity for chemical analysis and to draw from the conductivity measurement conclusions on the amount of impurities in the water. It can be applied to measure hardness in water, leakage of cooling water into surface condensers, sewage pollution in rivers, minute traces of impurities in distilled water, the priming of steam boilers, etc.

It is clear that conductivity measurements do not discriminate between one kind of foreign substance in the water and another and that analysis alone can do that. But in most instances in which water testing is carried out for engineering purposes, the substance present in the water is known, having been ascertained once for all by analysis, or being inherent in the source of supply. Further tests are then not made for purposes of analysis, but to find out how much of the known substance is present in the water; and in all these cases the dionic tester gives the required answer with a rapidity and simplicity unapproached by any chemical test.

For instance, whenever it is important to keep a check on the purity of a water supply, the use of the dionic tester enables all analyses subsequent to the initial one to be dispensed with, until such time as change in the conductivity indicates an alteration in the proportion of dissolved substances present in the water. All that is necessary is to have a sample of the water analysed and at the same time measure its conductivity. Thereafter it is only necessary to measure the conductivity at frequent intervals, and so long as there is no marked change in the value obtained, there is certainly no appreciable change in the purity. These routine measurements do not occupy more than a couple of minutes each, nor do they require a skilled man to make them. Hence the cost of testing is practically confined to the initial outlay upon the apparatus.

The construction of the dionic water tester of Messrs. Digby and Biggs is exceedingly simple. It is shown diagramatically in Fig. 1 and an outside view is given in Fig. 2. G is a bent

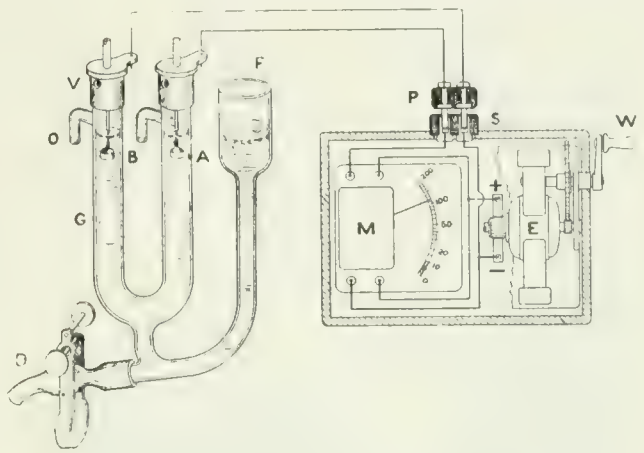

FIG. 1.—DIAGRAM OF DIONIC WATER TESTER.

glass tube to contain the water under test, and A and E are the electrodes for passing the electric current through the water. The electrodes are connected by wires to a direct-reading conductivity meter M, and a direct-current hand-driven dynamo E; so that by turning the handle W of the dynamo, a current traverses the meter and the water in the conductivity tube G. The pointer of the meter is deflected, and comes to rest at some point upon the scale which directly indicates the conductivity of the water in the tube. The test is completed as soon as the pointer has come to rest, that is to say, in two or three seconds.

The tube G is made long enough, and the electrodes are given sufficient surface, to make the electric resistance in the parts of the current-path immediately surrounding the electrodes negligibly small compared with that of the length of water in the tube. Hence, gas bubbles may accumulate on the electrodes without making any observable difference in the measured conductivity. The electrodes are short hollow cylinders of platinum so that they present a large surface, from every part of which gas bubbles are free to escape upwards.

The counter e.m.f. of polarization set up in the cell during the measurement is taken care of in advance in the calibration of the scale of the conductivity meter. Evidently, any back-electromotive force will make the conductivity of the water in the tube appear to be less than it really is; and what is done is to mark the divisions on the scale so that they represent the true conductivity of the water. To do this it is necessary to take a fair average-value for the back-electromotive force of polarisation. With bright platinum electrodes in a dilute salt solution the back e. m. f. is about 2 volts, and this is the value allowed for in marking the scale.

The dynamo generates a constant pressure of 100 volts, so that any variations in back e. m. f. above or below two volts are negligibly small by comparison and do not produce any observable error. To maintain the necessary constancy of pressure the dynamo is fitted with the constant-speed clutch, which Mr. Evershed introduced several years ago for insulation testing purposes. The effect of this device is to keep the pressure con-

stant at 100 volts within one-quarter of a volt, when the dynamo handle is driven at any speed above that at which the clutch is adjusted to slip.

A correction for temperature variations is easily applied.

Conductivity or specific conductance is the reciprocal of resistivity or specific resistance the unit of which is the megohm. The unit of conductivity is the reciprocal of one megohm and has no special name; the scale of the dionic water tester extends from zero up to 2000 such units.

The conductivity tube is so constructed that by pouring water into the funnel F, and allowing it to overflow through the outlet pipes OO, every part of the tube is thoroughly washed out, and any products of electrolysis which may have accumulated upon the electrodes are at the same time swept away by the water. The air vents VV ensure a steady flow from each outlet without any syphoning action. A drain pipe D of pure rubber is provided at the bottom of the tube for the purpose of drawing off the contents at the conclusion of a test. Normally, the drain is closed by a pinch-cock. Water may be left stand-

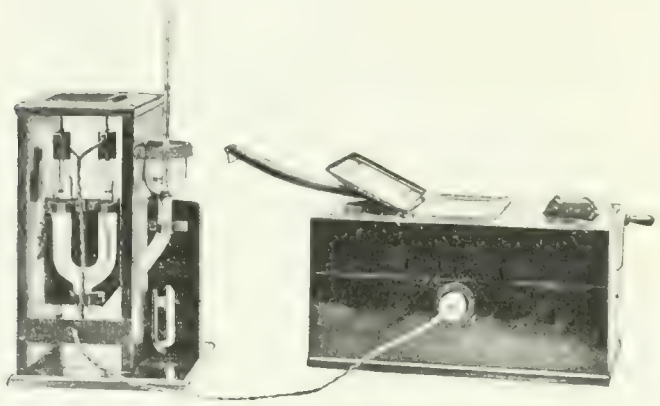

FIG. 2. DIONIC WATER TESTER READY FOR TEST.

ing in the tube for days at a time without the slightest trace of contamination from the rubber finding its way into the conductivity tube. The other materials in contact with the contents of the tube are glass and platinum.

The tube is mounted on a strong teak stand designed to afford as much protection as is consistent with accessibility.

The conductivity meter and dynamo are fixed inside a box and once for all connected up to each other and to the terminals of the socket S, which is fixed on the outside of the box. The two-pin plug P is permanently connected up to the electrodes A and B by means of a short length of well-insulated twin-flexible cable. Hence, all the user has to do in order to connect the tube to the meter is to push the plug into the socket.

The dynamo and conductivity meter do not need any attention, and, in fact, the box containing them is closed and sealed by the makers. The dial is visible through a window in the top of the box, and the handle of the dynamo is folded back into a recess when not in use.

The applications of this method to control of the hardness or softness of water, to the detection of leakage into a surface condenser, to tests of purity of distilled water, etc., are described in some detail in the pamphlet.

Concerning the control of purity of distilled water Mr. Evershed remarks: "The water tester easily detects the presence of traces of electrolytic substances in distilled water so small that they would entirely escape the analyst. One of the discoveries I made with Messrs. Digby and Biggs' apparatus was that specially distilled water, sold by wholesale chemists at four shillings the gallon as being almost the purest water obtainable, was hardly any purer than ordinary distilled water purchaseable at any chemist at a few pence per gallon. The discovery led to a considerable improvement in the specially distilled water, the conductivity of which does not now generally exceed 2 units. Pure distilled water is essential for many purposes and, so far as I know, the conductivity test is the only simple means of ascertaining the degree of purity. By simple, I mean that an accurate test can be carried out by an unskilled person in about five minutes, and that no laboratory is needed."

There are several interesting appendices, one on the conductivity of mixtures, the second by Mr. F. E. Pollard on dissolved substances commonly found in water used for steam boilers, and the third giving a table of the conductivities of various waters.

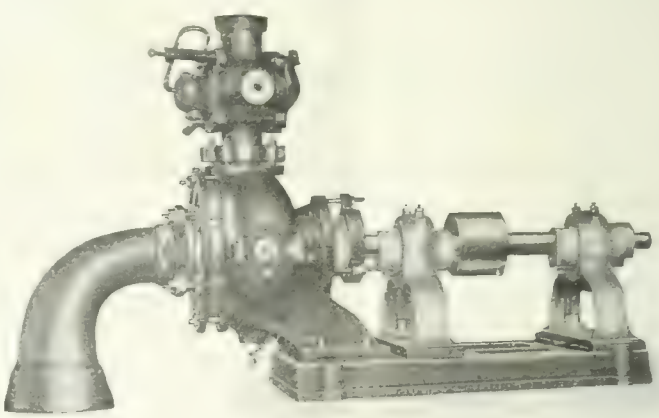
Clearly the dionic water tester will not replace chemical water analysis in every case, but there are innumerable cases in chemical and industrial practice where after a single chemical analysis has been made the dionic tester can be used continuously for control for the purity of the water and can render any further chemical analysis superfluous until a change in the conductivity indicates directly the necessity of making a new one. In view of its extreme simplicity of construction and ease of use the dionic water tester should prove very handy in large-scale practice. It is being placed on the market in this country by Mr. James G. Biddle, 1211 Arch Street, Philadelphia, Pa.

A New Acid-Proof Pump.

By Percy C. Kingsbury.

The centrifugal pumps made of chemical stoneware by the Didier-March Company, of 30 Church Street, New York City, are so well known in the chemical and metallurgical industries that a short description of their latest improved model will be of interest.

One great advantage of the new design is the ease with which the interior of the pump may be examined. By loosening a few nuts the cover forming the front face of the body may be removed, exposing the impeller and allowing a thorough



STONEWARE PUMP.

inspection of the working parts. The impeller is so designed as to be readily interchangeable in case of damage by the introduction of foreign matter into the pump. The general dimensions of the pump have been retained so that the replacing of an old style pump by the latest pattern entails no disturbance of existing pipe lines. In changing this standard pattern the opportunity has been taken to make a number of minor mechanical imrovements in the design, the depth of the stuffing box having been increased and the inlet of the pump made considerably larger, thus reducing the friction in the pipe line on the suction side.

All the advantages of the old-style pump are retained. Nothing but acid-proof chemical stoneware comes in contact with the liquid. The stoneware parts are accurately ground and balanced, making the action of the pump very smooth and quiet. The cast-iron casing into which the pump is grouted

effectively prevents any possibility of damage from external causes or from internal pressure. The stoneware elbow shown in the illustration is supplied with the pump and is used for connecting to a foot valve when required. This foot valve can also be obtained made entirely from chemical stoneware. The three-way cock serves for priming the pump and is also supplied.

The greatest care is given to the manufacture of the stoneware impeller which in the smallest size pump runs at 1500 r.p.m. All impellers are tested at 50 per cent of their rated speed before the pumps are assembled. A series of experiments have been carried out on these pumps by Professor Schulze-Pillot at the German works of the Didier-March Company to establish by actual operation under working conditions their efficiencies and capacities under various heads and at various speeds. Reliable information in regard to the use of the pumps for different purposes is therefore available. An experimental station will shortly be ready at the factory of the Didier-March Company, Keasbey near Perth Amboy, N. J., where parties interested may see these pumps in operation.

In handling acids and other corrosive liquids the continual breaking down of metallic pumps with the constant repair and lost time has been a serious problem, frequently involving danger to workmen and property. An incorrodible pump of practical design, developed by years of experience, should prove a satisfactory solution of many such difficulties and has, in fact, for many purposes proved to be absolutely indispensable.

Steam-Jacketed Kettles, Mixers, and Vacuum Pans.

The Sowers Manufacturing Company of 1302 Niagara Street, Buffalo, N. Y., have just issued a profusely illustrated catalog (Catalog V, section 1) on the steam-jacketed kettles, mixers and vacuum pans of their make.

Since the H. W. Dopp Company was taken over by the Sowers Mfg. Co. the well-known Dopp seamless steam-jacketed kettle is now being manufactured by the latter company, and in view of their greater manufacturing facilities some interesting advances in its construction have been made.

The Dopp kettle is seamless, so that all joints are done away with. The inner and outer shells are absolutely cast in one piece, thus avoiding joints and rivets, and the inner and outer shells are tied together by a system of oval stay-bolts cast at the same time as the shells. This construction permits the use of thin shells, which means a highly efficient kettle through perfect circulation and quick radiation.

By the system of molding used by this company sand does not come in contact with the inner and outer surfaces of Dopp kettles. This insures a perfectly clean and smooth casting, without the necessity of grinding the surface for a smooth finish, which destroys the hard skin valuable to the life of a kettle. The catalog gives illustrations and data on different types and sizes of these steam-jacketed kettles, and especially on the different types of standard outlets used in connection with them.

The second part of the catalog gives a series of illustrations of steam-jacketed agitators and mixers with various arrangements of the paddles, scrapers, screws, etc., to provide the specific mixing operation required in any case. These mixers being steam-jacketed, also permit quick and effective cooling, when necessary, by running cooling water through the jacket.

The concluding part of the catalog is devoted to seamless jacketed vacuum pans.

The basis of these vacuum pans is again the Dopp seamless steam-jacketed kettle used as the lower half. The dome being practically the same shape as the kettle, makes a very symmetrical and strongly proportioned piece of apparatus. The pans are cast by the same special process which gives to Dopp kettles their smoothness and strength. This makes them particularly well adapted for use where a perfect surface and cleanliness are desirable and necessary.

These vacuum pans are made in 15 standard sizes, ranging in capacity from 10 to 1300 gallons. Various types are shown in the illustrations in the catalog, some of them provided with agitating devices, also steam-jacketed antoclaves or digestors, for use in the manufacture of materials which require cooking under pressure.

The catalog, which is concluded by data on and illustrations of vacuum pumps, is well worth the attention of the many users of steam-jacketed apparatus in the chemical industries.

A New Protective Coating for Iron and Steel.

Since the introduction of sherardizing into commercial practice a few years ago, the Lohmannizing process to be described in this article is probably the most interesting and novel development in the endeavor to find a new solution of the ever-burning problem of providing a really protective coating for iron and steel.

If we leave aside protective paints, protection has generally been sought in the past by means of zinc coating. There are three zinc plating processes at present in extensive commercial use: the old "hot galvanizing" process, the electrolytic zinc plating or "cold galvanizing" process, and the more recent "sherardizing" process. Concise descriptions of these processes, as well as critical comparisons between them, may be found in an extensive article by Mr. Sherard-Cowper-Coles in our Vol. VI, p. 189 (May, 1908).

The process of Lohmannizing, called after its inventor, Mr. Herman J. Lohmann, differs distinctly from the processes just mentioned in so far as it is by no means restricted to zinc coatings, but may be used for coatings of zinc, lead, and tin in varying preparations to suit the requirements of each case.

The patents for the process are owned by the Lohmann Company of 50 Church Street, New York City, which is introducing the process into commercial use by granting licenses.

Licenses have so far been granted to the Brier Hill Steel Company of Youngstown, Ohio, and to the DeForest Sheet & Tin Plate Company of Niles, Ohio.

The Erie Railroad Company has also used the process quite extensively during the past two years for plating whatever was suitable around their locomotives, and has achieved excellent success.

The Lohmannizing process is very similar to the old hot galvanizing process. The similarity is indeed so close that workmen who are accustomed to work on the hot galvanizing process can be put immediately on the Lohmannizing process without even knowing it, since the chief difference is that instead of the muriatic acid bath used in hot galvanizing just before the article enters the spelter bath, the so-called Lohmann bath is employed as will now be described. The following description is based partly on an account given out by the Brier Hill Steel Company and partly on the patent specifications.

The process begins as usually with pickling the iron and steel in a bath of sulphuric acid. This pickling treatment removes rust, dirt and scale in the well-known manner from the surfaces which are to be coated.

Now the article is dipped into the Lohmann bath, which, "being composed of an acid and an amalgamated salt, further cleanses the pores and cavities, and deposits metallic salt upon the entire surface, penetrating into the most minute pores and cavities." According to the patent specification the Lohmann bath is a solution of hydrochloric acid, bichloride of mercury, and salammoniac. The essential new feature is the bichloride of mercury.

Now follows drying and then immersion in the molten protective alloy which is at a temperature of 950 to 1000 deg. F. "An amalgam or chemical union is thus formed between the amalgamating salt and the protective alloy." In contact with the molten alloy the temperature of the immersed iron or steel article gradually rises. When it reaches a temperature of 500

deg. the mercury volatilizes, is released, and rapidly comes to and passes from the surface of the alloy.

While this occurs the complete surface of the treated metal, especially its pores and cavities, are left free and open for the protective alloy to fill them up and enter into a perfect union with the iron and steel surfaces, there being a complete freedom from oxidizing influences.

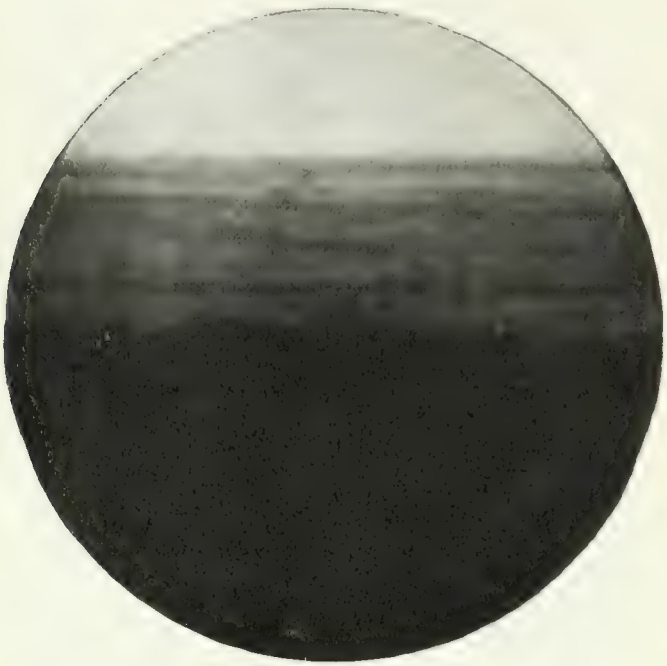
In this way it is possible to get a perfectly satisfactory lead plating as is not possible with other methods.

The chief points of the process are that the junction between the iron and steel and the protective alloy is not only maintained chemically pure and free from oxides, but is also mechanically intimate.

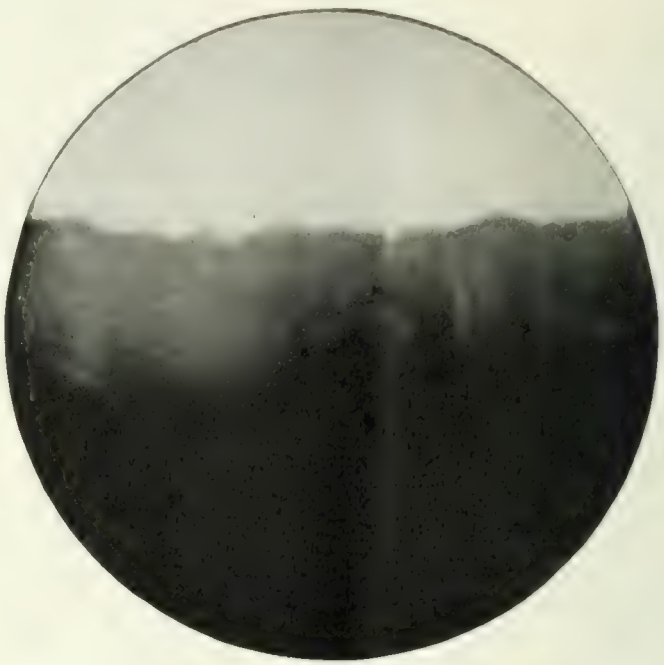
It is also possible to use the Lohmann process for zinc plating or for applying a protective alloy of zinc, lead, and tin in any proportions.

For instance, a coating of 100 zinc, 4 lead, and 1 tin is useful as a substitute for galvanized sheets where it is desired to make the sheets more resistive and pliable.

A coating of 10 lead, 1 zinc, and 1 tin is useful for articles where extreme pliability is not needed and where a bright appearance is desired in the finished article. Of course, such a coating is not as resistant as straight lead.



GALVANIZED SHEET.



LOHMANNIZED SHEET.

That this result is really obtained is confirmed by the microphotographs of the cross-section of a hot galvanized sheet (Fig. 1) and of a Lohmannized sheet (Fig. 2), both being magnified 65 times. For these microphotographs we are obliged to the Brier Hill Steel Company.

Fig. 1 indicates that the coating on a hot galvanized sheet resembles in its nature a coat of paint. The spelter coat, when thick as it should be, is liable to crack. When thin it is porous. In either case the iron sheet would be unprotected. Also minute particles of the acid used in pickling or cleaning the metal are liable to be carried over on the sheet, through the spelter pot, and finally be included between the sheet and the coating. The acid in time causes oxidization, the coating is bulged out from the sheets and, at least, it crumbles and chalks, leaving only the bare sheet.

Fig. 2 shows, in the case of Lohmannized sheet, the permeation of the sheet surface by the alloy. This continuous alloying zone between the outer coating and the underlying iron and steel cannot be ruptured in such a way as to leave the sheet exposed without fracturing the sheet itself, so that the sheet is always protected. Also the "amalgamating salt" of the Lohmann treatment cleans the sheet absolutely and itself evaporates wholly as the sheet receives the alloy, thus insuring the absolute elimination of all oxidizing agents such as would naturally cause crumbling and destruction of the spelter layer.

The underlying idea of Mr. Lohmann's work was to get away from pure zinc plating. As described it is possible to obtain a pure lead plating by the Lohmann process. To our chemical readers who daily use lead-lined apparatus the applications of this process for such purposes are evident. But

It will be easily seen that according to the requirements of each case the composition of the coating can be varied. It should be added that the chemicals used in the process are quite inexpensive, while the use of lead means, of course, a considerable saving.

The Lohmannizing process certainly desires careful watching in its introduction into commercial practice.

Non-Ferrous Metal Market.

Copper and lead have been almost without feature since our last report. Tin has fluctuated somewhat, and the market has been affected by the English coal strike which, it was thought, might seriously affect shipments and cause a shortage. Spelter has been rising steadily, although the market has shown wide variations in prices.

Copper.—This market has been without feature, and sales have been small owing to the high prices asked. The principal sellers have maintained their prices in spite of the dull market, and feel hopeful that sales will increase at the advance asked. The latest reports quote Lake at 14½ to 14¾ cents per pound, and electrolytic at 14.40 to 14.45 cents.

Lead.—The leading seller has continued to meet all demands at the uniform price of 4 cents, New York, and 3.95 cents, St. Louis.

Tin.—The domestic market has declined in sympathy with the London market, which has been depressed on account of the English coal strike. Domestic buyers have kept out of the market largely and are awaiting developments. March tin was quoted at about 41⅞ cents.

Spelter.—Prices for this metal have risen steadily during the past month. The smelters seem to be well sold out and spot metal commands a premium. The market has been very

irregular and prices have varied widely. The last quotations are 6.65 to 6.95 cents, New York, and 6.50 to 6.80 cents, St. Louis.

Other Metals.—The market for aluminum is fairly good and the March price was about 19¼ to 19½ cents, New York. In antimony there has been little change and small volume of business; the prices vary from 6¾ to 7⅜ cents for different brands. The market for quicksilver is a little firmer and prices unchanged at $46 per flask of 75 lb. at New York and $45 at San Francisco.

Personal

Messrs. Charles H. Repath and **A. G. McGregor** have formed a partnership for the conduct of an engineering business, with a specialty of constructing metallurgical plants. They have been associated together in the construction of some of the largest plants in the West, and now have charge of other important works. Their office is at Douglas, Arizona.

Mr. H. Kenyon Burch is to have charge of the remodeling of the Old Dominion concentrator, at Globe, Arizona. He is now at Globe preparing plans and specifications.

Mr. Hiram W. Hixon has left Philadelphia to take charge of the smelting works of the Tezuitlan Copper Company, Tezuitlan, Puebla, Mexico.

Smith, Emery & Co., Los Angeles, are installing a complete ore-testing plant in connection with the chemical laboratory at Los Angeles, Cal.

Mr. F. W. Draper is to have charge of the design and construction of a new copper smelter at the Kalata mines of the Verk Isetz Corporation, of Ekaterinburg, Russia, and will also remodel the existing plant at the Pushminsky mines.

Mr. Cyrus Robinson, of New York, has charge of the installation of a new cyanide plant at Fresnillo, Zacatecas, Mexico.

Mr. A. J. Hoskin, formerly professor of mining at the Colorado School of Mines, has been appointed Western representative of *Mines and Minerals,* with offices in Denver, Colo.

Mr. George J. Hough, of Salida, Colo., has sold his assay office at that place, and will again engage in professional work as a metallurgist.

Mr. A. H. Brown, formerly metallurgist at the Nickel Plate property, Hedley, B. C., has accepted a position with the Hudson Bay Mines, Ltd., Cobalt, Canada.

Notes

Connersville Blowers at the Granby Smelter.—In the article on the Granby smelter in our last issue there is an error on the bottom of page 151 in so far as mention is made of only one 30,000-cu. ft. Connersville blower; but the picture shows four of these machines in one room, each driven by two electric motors. The Connersville Blower Co. considers this an ideal method of driving rotary blowers, because each impeller is driven independently.

The Goldfield Consolidated Mines Company, Goldfield, Nev., has issued its final statement of November, 1911, operations. The 100-stamp mill treated slightly over 954 tons per day, which is less than the high record for October. The cause lay in the time lost in relining tube mills and repairing Chileans. The average value of ore was $26.77 per ton, and the extraction netted $25.28 per ton, or 94.45%. The total cost of mining, milling, office and general expense was $7.49 per ton.

Ferrotungsten is produced electrically, according to the *Mining Journal,* by the Ampere Company, of Berlin. Scheelite is smelted directly with iron sulphide and carbon in an electric furnace, the iron sulphide acting as a flux. Lime also is added to flux the silica in the scheelite. The reaction given is as follows:

$$CaWO_4 + FeS + 4C = FeW + CaS + 4CO.$$

The lime silicate slag carries the calcium sulphide formed according to the reaction.

The Serpek process of nitrogen fixation consists in heating bauxite with coal at a temperature of 1700 to 1800 deg. C. From 15 to 18 per cent nitrogen is absorbed as aluminium nitride. The nitrogen-carrying bauxite is then treated with caustic soda, whereupon ammonia is evolved and caught. The profit from the ammonia reduces the cost of alumina and aluminium.

The production of tungsten ore in the United States was not recorded previous to 1900; before that time it was insignificant, and it is only since 1906 that the data have been kept in a manner to make comparisons possible. The output since that year, expressed in short tons of 60% tungstic acid content, is as follows: In 1906, 928 tons; 1907, 1640 tons; 1908, 671 tons; 1909, 1610 tons; 1910, 1821 tons.

The output of tin-plate mills in the United States has shown a rapid increase in the past two decades. In 1892 the total output of American mills was 18,803 tons; in 1900 it had risen to 302,665 tons, and in 1910 it reached 725,000 tons, making the United States the world's chief producer of tin plate. Statistics regarding imported plate and re-exported containers show that practically all the plate imported in 1911 was again sent out of the country as manufactured cans, etc.

The approximate value of silver ore and concentrates shipped from Cobalt, Canada, during the last six months of 1911 was $6,247,077. There are now 16 concentrating mills in active operation in the Cobalt district.

The heat of formation of titanium dioxide has been determined by W. G. Mixter to be about 218,000°. His best results gave 218,400°, and the mean of seven experiments was 218,500°. Mr. Mixter was led to repeat his previous work, in which he obtained a figure of 215,600, on account of the work of German investigators wno gave as the average of their experiments the figure 97,772. The full details of Mr. Mixter's work are published in the *American Journal of Science,* for January, 1912.

The slow-speed Chilean mill is essentially a fine grinder. Where ore is to be crushed to ¼ in. in stamps and then ground to 30 or 40 mesh in tube mills, the slow speed Chilean cannot compete, but as a fine grinder it is regarded by many engineers as having a high mechanical efficiency.

Scaling Amalgamated Plates.—The following procedure is adopted in South Africa for removing the hard scale of amalgam which forms on copper plates after they have been in service for a long time. The plate is heated over a wood fire to drive off all the mercury, the heat being just sufficient to char saw-dust thrown on the plate. It is then removed, and while fairly warm is painted with strong hydrochloric acid. After standing over night the plate is painted with a mixture of equal quantities of saturated solutions of saltpetre and sal ammoniac, and heated again over a bright wood fire. At this stage the scale rises, and after removal of the plate from the fire may be brushed off. The treatment of the scale is similar to that of zinc-gold slime. Usually the first scaling will remove most of the gold, but a second operation will give a slight additional recovery.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in November, 1911, was 68. The total tonnage milled during that period was 2,138,594 tons of ore; 10,162 stamps were in operation with an average duty of 8.01 tons per 24 hours. Tube mills in commission numbered 243. The yield for the month was 719,729 fine ounces gold. The record for the first eleven months of 1911 eclipses that of the entire year 1910.

The Leadville Mines Pumping Company has received favorable responses from many of the owners of Fryer hill properties, and has prepared plans of operation so that when perfect co-operation is finally assured no time will be lost in getting the project under way. Carefully drawn contracts

based on fairness and justice to all concerned will soon be ready to send to various owners and lessees for their signatures.

The Ore Concentration Company, Ltd., reports that during the month of January the Elmore plant at the mines of the Sulitelma Copper Company, Norway, produced 720 tons of copper concentrate.

Bleaching Powder.—In a paper by R. L. Taylor, originally presented before the (British) Chemical Society (*Journal,* Vol. 97) and recently republished in the *Journal* of the Municipal School of Technology, Manchester, Vol. IV, the following conclusions are reached: The action of carbon dioxide on bleaching powder and similar substances results in the liberation of chlorine only—no hypochlorous acid. The conclusion is drawn that the action is like that of any other acid, and that carbonic acid decomposes both the chloride and the hypochlorite in the bleaching powder. It follows from this that the action of hydrochloric acid on carbonates is a reversible one. Ordinary moist air acts on solid bleaching powder, liberating at first both chlorine and hypochlorous acid, the former in much the larger amount. After a time nothing but chlorine is produced. When ordinary air is passed through a solution of bleaching powder, a mixture of hypochlorous acid and chlorine is swept out, at first in about equal amounts, but as the experiment proceeds, the former diminishes and the latter increases to about 90 per cent. The action of chlorine on alkalis, like that of iodine and bromine, is a reversible one, as stated by von Tiesenholt. If the free lime in bleaching powder is removed, this causes the reverse action to proceed and thus chlorine is liberated. This explains the action of ordinary air on bleaching powder. The reversibility of the action also explains the stimulating effect on bleaching which the addition of calcium chloride or of salt causes in a solution of bleaching powder. In the ordinary processes of bleaching the active bleaching agent is probably free chlorine, hypochlorous acid playing only a minor part.

The firm of **Robt. W. Paul** of New Southgate, London, England, manufacturers of electrical standard and testing instruments, has opened a branch depot and laboratory at 1 East 42d Street, New York. This branch is in charge of Mr. Cuthbert J. Brown, who for some years has been engaged in the testing department of Mr. Paul's works, and who will be responsible for the good condition and accuracy of the instruments shipped to purchasers in this country. We have received an abridged catalog containing particulars of the very large range of instruments manufactured by Mr. Paul, including a series of moving-coil instruments on the unipivot principle. These instruments are robust and free from the necessity of leveling, although they have an extremely high sensitivity and can therefore be used in place of reflecting galvanometers for many tests, as well as forming convenient resistance millivoltmeters and microammeters.

BOOK REVIEWS.

Sulphuric Acid and Alkali. Vol. III: Ammonia, Soda, Alkali and Chlorine. By **G. Lunge.** Third edition, 6 x 9 in., 764 pages, 184 illustrations; price, $10 net. New York: D. Van Nostrand Company.

The venerable mentor of the acid and alkali industry gives us again a painstaking and detailed revision of his third volume. He includes in it chapters on bleach and chlorates, but excludes electrolytical methods, which are to be handled by Professors Haber and Askenasy, and published later as Volume IV.

Dr. Lunge's many friends rejoice that he is still able to render such signal service to the chemical industry; his wonderful volumes have served not only as a *vade mecum* to the acid and alkali industry, but have set a standard in scientific treatises which has benefited by its example the whole field of technical literature.

Messungen elektromotonischer Kräfte galvanischer Ketten mit wässerigen Elektrolyten. Gesammelt und bearbeitet in Auftrage der Deutschen Bunsen Gesellschaft von **R. Abegg, Fr. Auerbach** und **R. Luther.** 16 x 24 centimeters, 213 pages; price, bound in paper, 8.40 marks. Halle a.S: Wilhelm Knapp.

The aim of this work is to present "a tabulation like that of Landolt-Bornstein-Meyerhoffer's for physico-chemical data, which shall give in this field a complete review of all the investigations so far made, in order to facilitate the use of these data for chemical purposes." The volume contains three distinct sections: (1) A systematic, chronolgically arranged list of all the literature of such measurements; (2) a systematically arranged selection of the most reliable results of such measurements; (3) tables of the present most probable values of single potentials. For carrying on the work, the authors request the co-operation of all persons making such measurements, by sending of results to Dr. Auerbach, care of the publishers, Wilhelm Knapp, Halle a. S., Germany.

Galvanostegie. I Theil: Uber elektrolytische Metallniederschläge. Von Dr. Ing. **M. Schlöffer.** 17 x 24 centimeters, 257 pages, 22 illustrations. Price, in paper, 12 marks. Halle a.S.: Wilhelm Knapp.

The author was practically engaged in the Langbein-Pfanhauser Works. He intends the book to present not merely the facts of electroplating and the composition and handling of baths giving good results, but a scientific discussion of the "why" and "wherefore," as far as such explanation can be given. Writing on this plan, the author has made a very instructive and interesting book. His chapter on the influence of colloids in metal plating is a valuable contribution to the subject, and the same may be said of a 30-page chapter on the deposition of alloys. The book is worth careful study by all intelligent electroplaters.

Metallurgy. Vol. I: Introductory. By **Herbert Lang,** 6 x 9 in., 255 pages, 24 illustrations; price, $3 net. New York: McGraw-Hill Book Company.

Mr. Lang is known as the author of a small practical book on "Matte Smelting," and he now puts into effect a plan of sixteen years' standing, *viz.,* to discuss the fundamental principles of metallurgical processes and the essential features of metallurgical apparatus and appliances. As the author says, metallurgical literature is rich in descriptive works, but lacks a comprehensive study of "the reasons why." The lack is not so glaring at present, we may remark, as it was sixteen years ago, when the plan of this work was conceived, but there is still room for such a work if written by the right man and in the right way.

This introductory volume covers only a few topics: *viz.,* ore crushing, sampling, roasting, smoke and fume. Volume two will include smelting processes, and volume three amalgamation and wet methods. In the chapter on ore crushing the author has very cleverly attained his object; the discussion of principles, illustrated by a few examples of apparatus, is excellent and will prove very instructive. Sampling is similarly treated, but not so fully. Roasting is voluminously explained, but not in terms quite as exact or definite as the present state of metallurgical knowledge would warrant; the *rationale* of self-supporting roasting is not treated as thoroughly as it should have been, particularly in connection with pot roasting. However, these are minor omissions in a very well-written and illuminating chapter. Smoke and fume are handled excellently, with some original ideas as to why and wherefore, however, which are not accepted everywhere as orthodox.

The style is familiar, and will appeal to the student; the English is not excellent, but is usually clear; the explanations are necessarily colored by the author's preferences, but are generally sound and in all cases put in a way stimulating to observation and thought.

It is a useful book, which has an undoubted welcome awaiting it in metallurgical circles.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. X | New York, May, 1912. | No. 5

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

J. W. Richards, Ph.D., President.
James H. McGraw, Vice-President.

Growing Up.

The entrance of the American Electrochemical Society at its recent meeting upon its second decade of activity is not, as it happens, an event of merely the usual birthday significance. The Society is becoming "grown up." The increase in membership is not only proceeding with a steadiness which, coming after the first flush of exuberant enthusiasm, marks a continual growth of interest, but it also has most desirable qualitative features. The phenomena of the Society's internal growth are, however, even more striking. Not a few members who attended the interesting colloquium on electrical conductance must have been struck by the extreme difference in the atmosphere of the meeting as compared with that prevailing some years ago. One recalls the rather ill-informed and sometimes contemptuous treatment which used to be meted out by many members to every reference to the ionic theory, which was at that date, within obvious limitations, generally accepted and used to the limit for what it was worth in all societies dealing with the same and allied subjects. What a contrast to the intelligent interest manifested in the Boston symposium on conductance, which turned out to be in large measure a discussion from many points of view on the electronic hypothesis.

It is not well to push parallelism too far, but we cannot help feeling that the explanation is to be sought in the evolution of the electrochemical industry itself. As is usually the case, this industry was based in its inception upon the pioneering work of men who were often brilliant technicians first and scientists second; but the growth and development of the industry have placed it, as again is normally the case, in the hands of men who are not only technicians, but scientists. This change has not been without its influence upon the personnel of the Society, and if we mistake not, it is this change that is responsible for the encouraging phenomenon noted above. It cannot be contended that the electronic hypothesis is likely to have any important direct bearing upon the progress of the electrochemical industry, and it may therefore be taken as granted that it is not a species of "enlightened selfishness" that leads a society, essentially technical in its nature, into these fields of hypothesis. The matter may rather be taken as an indication that the men who today are active in the field of technical electrochemistry are largely men of scientific training who keep bright their interest in pure science, not only for what it will bring but for what it is.

It is this happy interplay of the pure and technical sides of the subject that made the Boston meeting notable. There are some who will have noted how characteristic of this meeting it was that one of the most important papers dealt with the measurement of temperatures in the silicon carbide furnace and that the discussion on thermal conductances brought out a complete acknowledgment of the other fellow's point of view

and of the value of the other fellow's work from the advocates both of the empirical and theoretical methods of attacking problems in this field. How different again from those past meetings in which the advocates of these complementary methods in other fields steadily refused to recognize that the other man had any point of view at all!

Certainly the Electrochemical Society is becoming grown up. Perhaps it will now discard the pink pinafore of its lusty childhood.

Laboratories for Metallurgical Education.

It is a striking coincidence that two prominent schools of mines, one in the United States and one in Europe, should adopt at practically the same time a radical departure in methods of instructing students in the practice and art of metallurgy. We refer to the erection and equipment of large, commercial-size ore dressing and metallurgical laboratories at the Colorado School of Mines, and at the Royal School of Mines in London. The latter has been completed and formally handed over to the college governors, while the former is partly equipped and soon will be ready for use.

Since opinion is divided among technical educators as to the advisability of "large-scale" or "small-scale" laboratories for metallurgical instruction, we are frankly interested in the future of these two notable examples of the former type, and especially in the one at Golden. It is a pioneer experiment, and as such will have many problems to solve. Fortunately, those who are responsible for the innovation at Golden have long realized the magnitude of their undertaking, and have endeavored to develop in a satisfactory manner the varied relations which the plant will sustain to education and commercial ore testing.

On another page in this issue, Dr. Alderson, president of the Colorado School of Mines, has outlined these relations as far as they have been developed. Perhaps it will be necessary, with accumulated experience, to modify and adjust these relations; but in addition to the educational features, it is expected that the plan will render valuable aid to engineers and alumni of the school who may wish to undertake more prolonged and detailed investigation than would be possible with private facilities. In this way, the commercial features of the laboratory will not encroach upon private enterprise, but will supplement it, and will stimulate research and investigation which otherwise might not be undertaken. This, probably, is the largest problem, and in the solution of it lies, in a large measure, the success of the venture.

The Work of the Bureau of Mines.

It is becoming more settled that the relation of the federal Bureau of Mines to the metallurgical industry is to take a broad general form, as outlined in our editorial columns last February. The early agitation for government "testing plants" is dying out for the simple reason that the idea was ill-founded and without merit. On the other hand, both the Director of the Bureau and his associates who are directly charged with metallurgical investigations, have taken pains to familiarize themselves with the general situation, and have developed a tentative plan of action, subject to such modifications as further familiarity and experience shall direct.

Several points seem to be quite clearly settled. The government will not encroach upon private enterprise nor start investigations in those branches of metallurgy which are being so wonderfully and rapidly developed by individual members of the profession. This at once disposes of the bogey of government assay offices and testing plants. On the contrary, the Bureau will make investigations in those fields which are not well developed, and which even may be unattractive to private enterprise. (Whether the inherent danger of this is realized, is not yet clear. Spending money for research is generally unattractive and may become more so by the action of the Bureau. This would be a real calamity.) The work of the Bureau is intended to be that of the pioneer, laboring far afield, and perhaps engaging in researches which promise no immediate return, and the results of which may be negative. There are problems which even our largest companies do not undertake to solve, because the prospect of gaining commercial advantage is very uncertain, or because the idea seems too academic or even chimerical. And yet, if there is a possibility that the research is worthy of consideration on account of the knowledge and fundamental data to be obtained, the Bureau would be justified in undertaking it. In short, the Bureau is to keep its investigations well in advance of those likely to be undertaken privately. By fostering such work and showing its value, the Bureau hopes soon to gain the cooperation of private investigators and even hopes to stimulate research in those places where too little attention now is paid to it.

The recovery of by-products and the development of uses for them is to be made a special field for the Bureau's activities. Sulphur and arsenic at present constitute the two most important substances in this class, which can be recovered in large quantities, provided more extensive use can be found for them. Another line of work which may be undertaken is a study of the physics of ore slime, and the elucidation of principles which can be applied to slime concentration, which is admittedly the weakest point in ore dressing.

In the actual conduct of its work, it is expected that the Bureau will be enabled to make its researches at plants already established and working on a large scale. There will be a double advantage in this. First, the Government will not have to spend large sums of money in erecting plants for purely experimental purposes, in which the cost of research could not be offset by the profit which accrues to a going concern. Second, the results of experiments conducted on a large scale in a commercial plant will be of greater value than corresponding results obtained from laboratory work, for the latter sometimes are misleading when applied to operations on a large scale. While these advantages are evident, the danger is also evident that the work undertaken by the Bureau might be carried out in the interest of individual plants rather than in the interest of the whole public whose money is being spent, after all.

Clearly the problems involved in the organization of the work of the Bureau of Mines are not easy to solve. Their solution and the ultimate direction of the work must be left to the Director and his associates, who must be guided not only by their own wisdom, but also by the crystallized opinion of the better informed class of scientific and technical investigators.

The Titanic Disaster.

In the shadow of one of the greatest disasters of all time it may seem irreverent to speak of the sinking of the Titanic as furnishing suggestions in engineering, but there are phases of this terrible catastrophe which it seems particularly appropriate to mention in these columns.

One phase is the role which wireless telegraphy played in the disaster. Dreadful as was the disaster, it would have been more dreadful and more complete without wireless telegraphy. Thus again the work of the pure physicist has proven of eminent practical applicability. In view of the progress that has been made in this field, it seems remarkable that physicists should not yet have discovered a method of detecting the presence of icebergs from a distance with certainty. It seems even more remarkable that in these days where recording thermo-electric pyrometers and recording electric resistance pyrometers are in daily use not only in chemical, metallurgical and engineering works, but in various industries and trades, like bakeries, breweries, etc., the finest ocean liner built without regard to expense should have adhered to the method of getting up a pail of water every two hours and measuring its temperature. It reads like an anachronism.

There is another and more general thought suggested by the Titanic disaster. The progress in all branches of engineering is rapidly towards larger and larger undertakings, and the larger the structure the greater should be the unit strength of the material. Recent experience has shown that a steel passenger car can leave the track traveling at a speed of sixty miles an hour and dissipate its kinetic energy sliding over hard ground, without serious deformation. The Titanic, at the lesser speed of between 26 and 27 miles an hour, carried but one-fifth as much kinetic energy per unit of weight and was terribly deformed by a glancing blow upon ice, which may not even have absorbed all its energy of motion. Without entering at all upon the engineering principles involved in car and vessel construction, it is perfectly obvious that it is very much more difficult to make the larger structure safe. A small sphere may be made of thin gage sheet steel and resist deformation if projected at a great speed against a hard object, but a solid steel sphere can be conceived so large that it would crumble of its own weight.

As size increases the unit strength of material must increase, otherwise the useful function performed by the structure will decrease until it vanishes entirely and any larger structure would be unable even to preserve itself. A cable in a deep mine is a familiar illustration of this principle; for a given unit strength it can be made so long that it will break of its own weight. As engineering works increase in size their demand will be for steel of greater and greater unit strength, and steel metallurgy is building merely for the near future, for a demand which is certain to prove large, when it endeavors to produce, within commercial limits of cost, a steel of much greater unit strength than the steel now commonly employed.

Government Regulation of Industry.

In 1887 the original Interstate Commerce Act was passed. Ten years later the Supreme Court handed down its decision in the Maximum Rate Case, holding that the Commission had no authority to prescribe a maximum rate. Theretofore, the Commission had interpreted its authority under the law that rates should be just and reasonable as warranting it in prescribing that a given rate was unreasonable "to the extent that it exceeded" a rate which it named. Under the decision of 1897 a railroad could kill time almost indefinitely by making new rates graded downward by merely sensible gradations. Fifteen years later we find in practice a complete system of rate making by the Interstate Commerce Commission. It is easy to recall that when the first step was taken, only a quarter century ago, towards Federal regulation of railroads, the chief ground from the popular viewpoint which furnished the authority was that the railroads had been given the right of eminent domain. Today that fact is rarely considered at all as a basis for the federal authority.

There are those who stand aghast at the idea that the federal government should regulate the production and sale, as well as the transportation, of goods in interstate commerce, yet it is easier to conceive now in the light of experience, of such regulation being instituted, than it was fifteen years ago to conceive the present system of railroad rate regulation by the Interstate Commerce Commission, and it is well to reflect upon the wonderfully rapid progress this commission has made, as a means of conditioning our minds for the contemplation of federal regulation of the production and sale of commodities.

The work of the Interstate Commerce Commission is not a work accomplished. The work has only begun. What has occurred is that the commission has been delegated the authority, and the authority has been recognized by the institutions which are to be regulated. It is said by the experts, for instance, that in the decision in the Pittsburgh-Lake coal rate, rendered only this year, occurs the first instance of the Commission taking into serious consideration the cost of performing the service, in fixing a rate. Obviously, however, this is fundamental, and before the Commission lies practically the entire task of establishing a system of rates which are proportionate to the cost of the respective services, to replace a system in which the cost of performing the service only remotely enters in the case of any individual rate. For this task, of course, there is requisite the physical valuation of the railroads which the Commission has long requested means to make, and which is certain to be made within a very few years.

In the light of these developments the possibility of avoiding similar control over industries appears chimerical in the opinion of many, and it is emphasized that this is a definite constructive work, not to be purchased ready made at a bargain counter, but to be prosecuted step by step as in any engineering undertaking. But just because it is, sight should not be lost of the fundamental question whether regulation of the production and sale of commodities is possible at all in a free country. No individual, no corporation, however big, can do it; this fact has been settled by experience. And the fact that the federal government is so much bigger does not prove in any way that it *can* perform regulation of production and sales of commodities without changing the whole foundation of economic life. As we have pointed out, it is likely that government regulation will come some day and experience will then show how it works. It is a pity that this question can only be decided by actual experiment.

Bureau of Standards Analyzed Samples.

The Bureau of Standards, Washington, D. C., is now ready to distribute certain special steels, as follows: No. 30, chrome-vanadium; No. 32, chrome-nickel; No. 33, nickel. The fee for these steels will be $2.50 each. A renewal of No. 19, acid open-hearth steel, 0.2 carbon, will probably be ready before this notice appears in print. Until printed certificates can be had, the above steels will be issued with provisional certificates without details of analyses or description of methods.

The Iron and Steel Market.

Steel mills being well sold up, and having reached the point of being able to operate at full capacity, with a few small exceptions, the market on finished steel products was taken in hand early in April and a progressive stiffening in prices has occurred. The leaders in the upward movement have been bars, plates and shapes. Bars were first advanced to 1.15 cents, and after the middle of the month to 1.20 cents. Plates and shapes first stiffened up to 1.15 cents, then advanced to 1.20 cents and finally in the closing days of the month advanced to 1.25 cents. To the keen observer the movement partook more or less of the nature of a "controlled market" though there is no definite price agreement in the trade. There remains a disposition on the part of the different mills to co-operate. This disposition is not strong enough to prevent price cutting when there is not enough business to go around, but when mills are well filled with business it requires no great sacrifice to advance prices.

Effective April 11 the American Sheet & Tin Plate Company advanced its prices about $2 a ton, establishing minimum quotations of 1.40 cents on blue annealed sheets, 10 gage, 1.95 cents on black sheets, 28 gage, and 3.00 cents on galvanized sheets, 28 gage. While the independents did not adopt the new minimum quotations at once there has been a disposition to withdraw the lowest quotations and the whole market is measurably firmer in this branch of the trade.

Taking the finished steel trade as a whole, buyers have contracted to purchase more material than they can use and producers have contracted to furnish more material than they can make, up to July 1. Contracts are not seriously regarded, as a rule, and amount to little more than options. The present price advances mean very little as to the average prices which will be realized on shipments to be made during the next two or three months, but they furnish a basis for higher priced contracts when these contracts expire. The question is really chiefly as to whether the mills will be strict in cancelling unspecified tonnages July 1. It is a question of unspecified tonnages, not of unshipped tonnages. The prospect is that they will be strict, as the market is in a relatively strong condition.

The steel trade as a whole is running at the rate of more than 90 per cent. of capacity. Some of the mills in the east are not operating full, and in some branches of the finished steel trade in the central west there is not full operation, but the situation as regards mill operations is entirely satisfactory. It is the best in about two years.

Specifications on contracts are naturally good when open market prices have been advanced above the price level in contracts, but specifications are not phenomenally good, and the probability is that jobbers and manufacturing consumers will specify for considerably less material in the third quarter than they are doing in the second quarter. This change would be likely to leave a gap later on, and weaken the market, but there are positive assertions made that the railroads will become heavy buyers within the next two months, and even a moderate increase in railroad buying would add greatly to the strength of the situation. It may be concluded that the steel industry is assured of practically full operation until after the November election.

Pig Iron.

There has been a fairly heavy [illegible] all districts. While purchases are not unusually large, considering the normal requirements of the individual purchasers, there is more buying ahead, betokening confidence in the situation and a general tendency of prices to advance. Steel making irons did not advance, except for an advance of 50 cents in basic iron in the East. In the Central West, the chief business was the purchase by the Republic Iron & Steel Company from valley furnaces of 40,000 tons of basic at $13, furnace, and an equal tonnage of Bessemer at $14.25, furnace. Quotations are as follows: Foundry iron, $10.50 to $10.75 for prompt and $10.75 to $11 for forward, Birmingham; $15 to $15.25, Philadelphia, $13.25, valley; $14.25 to $14.50, Chicago; basic, $15, Philadelphia; $13, valley; Bessemer, $14.25, valley.

Steel.

The month of April saw the withdrawal of nearly all the mills as sellers of billets and sheet bars, as specifications had been very heavy and the requirements of their own finishing departments had also increased. Finishing mills are well covered, as a rule, to July 1 and the market is not active, though with a very strong undertone. Billets may be quoted at $20 and sheet bars at $21, Pittsburgh, but these quotations are largely nominal. Rods are $25, Pittsburgh.

Finished Material.

As the market became strong Chicago disappeared again as a separate basing point for bars, plates and shapes. In 1909, and again recently, the idea became prevalent that on account of the increased production of the Chicago district it had become a separate basing point, but on the appearance of a stronger market the Pittsburgh basis renewed its control over Chicago. Competition can hardly be eliminated if separate basing points are in existence. Before the Chicago basis disappeared in April, bars, plates and shapes were quoted in Chicago at 15 cents per 100 lb. over the Pittsburgh basis, the actual freight being 18 cents. Chicago prices are now 18 cents above Pittsburgh prices.

Current price, f. o. b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Plates, tank quality, 1.25 cents.

Shapes, 1.25 cents.

Steel bars, 1.20 cents.

Iron bars, 1.25 cents, Pittsburgh; 1.27½ to 1.30 cents, Philadelphia, 1.15 to 1.20 cents, Chicago.

Sheets: blue annealed, 10 gage, 1.40 cents; black, 28 gage, 1.90 to 1.95 cents; galvanized, 28 gage, 2.95 to 3.00 cents; painted corrugated roofing, $1.35 per square; galvanized, $2.50 per square; according to the American Sheet & Tin Plate Company's new practice, inaugurated April 18, five cents per 100 lb. over the price of flat sheets for corrugating, and an additional extra for painting of five cents per square for gages 12-18, 10 cents for gages 19-24 and 15 cents for gages 25-28.

The Non-Ferrous Metal Market

The anticipation of fifteen-cent copper has been realized and exceeded, and a large volume of business has been transacted at a figure approaching sixteen cents. Most of this business was for foreign delivery, and much of it was with speculative interests. Lead has been erratic, and spelter sluggish with little demand.

Copper.—The feature of this market has been the lack of demand or even inquiry for Lake copper, practically the bulk of the business being done in electrolytic. The latest quotations are 15⅞ to 16 cents for Lake, and 15.70 to 15.80 for electrolytic.

Lead.—The St. Louis Market reached a parity with New York owing to the concentration of speculative business at the former market. Later, however, the St. Louis market returned to more nearly normal conditions. The last quotations are: St. Louis, 4.12½ to 4.15 cents; New York, 4.20 cents.

Tin.—A fair domestic business has been transacted for future delivery at slightly lower prices than those ruling abroad. Both foreign and domestic markets have been without feature. April tin was quoted at New York at 43 cents.

Spelter.—This market has been decidedly dull, with small tonnages moving for April, May and June deliveries. The tension in the spelter market is less than it was a short time ago. The last quotations are 6.35 to 6.55 cents, St. Louis, according to delivery, and 6.50 to 6.70 cents, New York.

Other Metals.—There has been a fair business in aluminum, but prices are firm at 20 to 20½ cents New York. Antimony remains steady at 6⅞ to 8 cents for various brands, and business is fair. The demand for quicksilver is good, but there has been a wide range in prices. The last quotations are $42 to $44 per flask of 75 lb. at New York, and $42.50 for domestic and $40 for export at San Francisco.

The Western Metallurgical Field.

Mason Valley Copper Smelter.

Reports of the operation of this new plant at Thompson, Nev., indicate that the one blast furnace in commission is far exceeding its rated capacity. Two furnaces of 400 tons capacity each were a part of the original plan of the smelter, but thus far only one has been in commission. Early in April this furnace was treating about 700 tons per day, and it is expected that this record will be maintained. The installation of a sintering plant has aided materially in raising the capacity of the furnace, for the sintered product is in almost ideal condition for furnace charge. In addition to handling the ores from the Mason Valley and Nevada-Douglas mines, the company is receiving ores from other smaller companies in the vicinity. Twelve companies are on the custom list.

Smelting and Agriculture in California.

It appears that the Shasta County Farmers' Protective Association is determined to keep on the trail of offending smelters and cause them to live up to the unfortunate terms of the court decree under which they can operate, and which provides that the gas issuing from the stack shall contain no SO_3, no solids, and shall not exceed 0.75 per cent SO_2. The farmers have recently considered proceding against the Mammoth plant of the United States Smelting Company, which recently expended several hundred thousand dollars in equipping the smelter with a bag house. The present complaint is to the effect that the bag house does not prevent damage.

In view of the unreasonable insistence of the farmers it is probable that the smelters may combine and ask permission to operate under an agreement to reimburse the farmers for damages. A commission of three men, one appointed by the smelters, a second by the farmers and the third by the court, may be organized to act as final arbiter in settling the amount of damage done. This arrangement is said to be under consideration by the United States company and the First National Copper Company, the latter having been out of commission for some months.

Further report is to the effect that the First National company is considering the installation of a new process to eliminate the sulphur from the fumes. Judging from the description obtainable, this refers to the thiogen process, which consists in reducing the SO_2 to sulphur by the reducing action of crude oil. This process is known to be in experimental operation at Campo Seco, Cal., under the direction of the inventor, Mr. S. W. Young.

Colorado.

The mining industry in this state, which has not been flourishing for the past few years, shows signs of improvement. Manufacturing and supply houses are reporting increased activity, and engineers have more work in prospect than for some time past. At Leadville, the local smelter has five furnaces in blast and is treating more ore than for two years past. This is regarded as an excellent indication of prosperity in the Leadville district, where smelting ores predominate. It is expected that when the roads are in better condition the tonnage offered to the smelter will be still greater.

Those properties which are producing zinc are working to full capacity in view of the excellent condition of the spelter market. At some properties which could not mill their ore during the winter there has been steady development work in the mines, and every preparation has been made for continuous milling as soon as the winter season is over.

It is reported that the Suffolk, which is the largest group of mines in the Ophir district in southwestern Colorado, is to be equipped with a cyanide plant this spring. There is now a stamp-amalagamation-concentration mill on the property, which has been in operation during the winter. Cyanide experiments have been carried on for some months with such successful results that the mill will be remodeled to include treatment by cyanidation. It is possible that amalgamation and concentration will be dispensed with, and the entire output of the mine cyanided. This is a distinct advance over the old method and will result in financial benefit to the company. The amalgamation recovery has not been high, and the cost of shipping and smelting concentrate has been so great that the net return to the company has not been as much as it will be under the cyaniding system. It is expected that the new plant will be in operation this summer.

Potash in Borax Lake, California.

A potash deposit of apparently great importance has been discovered at Borax, or Searles Lake, in the northwestern corner of San Bernardino County, California, and the value and extent of the discovery are now being investigated by the Bureau of Soils and the Geological Survey. The lake or playa in which the discovery was made is the last remaining pocket of a once much greater lake which has almost dried up, and in the central depression of which is a large body of crystalline salts known to consist of common salt, sulphate and carbonate of soda and borax. The salt body is saturated with brine, and interested persons stimulated by the government search for potash recently secured an analysis of an old sample of this brine. The result being significant, the lake was visited by representatives of the government bureaus, who took brine samples from six wells distributed over the salt flat.

Analyses of these samples have been made at the laboratory of the Mackay School of Mines, Reno, Nev. They show an average of 6.78 per cent potassium oxide in solution. The average salinity of the brine is 43.82 grams of solids per hundred cubic centimeters. Comparison of the results indicate that the brines are nearly uniform throughout the flat. The probable importance of this deposit is due to the occurrence of the potassium salts in soluble form in a natural saturated brine, and under climatic and other conditions favorable to its separation and recovery by solar evaporation.

Existing data give reasonable assurance that the brine-saturated salt body is at least 60 ft. thick and covers an area of at least 11 sq. miles. Assuming the salt body to contain 25 per cent by volume of the brine, the total amount of potassium oxide is estimated at over 4,000,000 short tons. This estimate is believed to be very conservative, and the available tonnage may well be expected to exceed 10,000,000 tons, which would supply this country, at present rate of demand, for thirty years. At any rate, it appears that this locality constitutes a very important source of potash in a form that probably is readily available for commercial use. Methods of separating potash from brines are now under investigation by the Bureau of Soils.

Company Reports.

The Old Dominion Copper Mining & Smelting Company, Arizona, has issued its annual report covering the calendar year

1911, from which we take the following interesting data. The average grade of ore mined and treated was as follows:

	1911	1910
	Cu per cent	Cu per cent.
Average smelting ore	7.75	7.85
Average concentrating ore	3.50	3.49

The concentrating operations are indicated in the following table:

	1911		1910	
	Dry tons.	Cu percent.	Dry tons.	Cu per cent.
Old Dominion ore	78,050	3.50	86,000	3.49
Custom ore	62,171	4.61	19,330	4.18

The cost of concentrating is shown below:

	1911	1910
	$1.012	$0.975
Dry tons concentrated	140,230	105,300

During the year there was purchased and installed a set of 36 x 16 rolls and a 6-ft. Evans-Waddell chilean mill, the total cost of which was $7,238, which amounted to $0.052 per ton of ore concentrated.

A comparison of smelting costs for 1911 with those of the previous year shows a material reduction.

	1911	1910
	$2.508	$2.029
Tons of ore charge smelted	231,603	239,162

Included in the above cost for 1911 is an expenditure of $16,359.50 for installing a mixing system, amounting to $0.07 per ton new charge smelted. The lower cost in 1911 is due mainly to the ore-mixing system, which was installed in 1910 and further perfected in 1911. It has done much to solve one of the most important problems, and has improved metallurgy and reduced costs.

The cost of converting per ton of fine copper was as follows:

	1911	1910
	$8.26	$9.68
Pounds fine copper produced	24,482,019	27,742,332

Power is produced in a battery of eight Sterling water-tube boilers, with a total rating of 2340 boiler hp, against the average requirement for the year of 1500 hp. The cost per hp-year was as follows: 1911, $83.77; 1910, $96.18. With the new contract for fuel oil, which became effective last October, power costs should be reduced 20 per cent.

United States Smelting, Refining & Mining Company.—An item in the sixth annual report of this company speaks eloquently of the difficulty of finding mining properties which are worthy the consideration of a large company. During 1911 921 properties were considered; 749 were declined without examination; 144 were partly examined; 28 were completely examined, and one was purchased.

Camp Bird.

The report to the effect that new discoveries of importance had been made in the Camp Bird mine, Ouray County, Col., has been confirmed by the London office of the company. The last annual report of this company acknowledged the depletion of the ore reserves, and intimated that the mine and mill would be operated only a part of this year unless new and unexpected discoveries were made. Apparently the unexpected has happened, and it is reported that the mine will have a further lease of life. This remarkably good fortune comes to a company which has been a leader in good mine management and good metallurgy.

CORRESPONDENCE.

The Lead and Zinc Tariff.

To the Editor of *Metallurgical and Chemical Engineer*:

Sir:—In your article upon lead and zinc tariff under date of March, 1912, some reference was made as to the sentiment expressed by mining men in Spokane regarding the entry of lead and zinc ores from Canada, which might lead the reader to infer that we are in favor of the free entry of such ores from Canada.

This, however, is not the case. As you know the production of lead and zinc scarcely meets the local demand in Canada and the cost of production is in excess of that in the United States, and for these reasons resolutions were passed some time ago favoring the entry into the United States of lead and zinc ores and their products upon a reciprocal basis.

As yet there is very little manufacturing done in Canada, the products of these metals being imported from the United States almost wholly.

There now seems little hope of any reciprocal relations with Canada, inasmuch as they are now advocating a tariff upon both metals.

L. K. ARMSTRONG.

Spokane, Wash.

Chemical Formulae.

To the Editor of Metallurgical and Chemical Engineering:

Sir: The writer has long been impressed with the unsatisfactoriness of chemical equations as found in the ordinary text-book, and for this reason recently made a brief investigation into the matter. Ten of the most popular works were selected and examined with reference to the reaction between lead nitrate and potassium chromate. Eight of the books gave the reaction as follows:

$$Pb(NO_3)_2 + K_2CrO_4 = PbCrO_4 + 2KNO_3$$

No comment was made, and the reader was left to infer that this is the only reaction to expect under ordinary conditions. Book number nine gave two salts, $PbCrO_4$ and Pb_2CrO_5. Book number ten gave these two, and $(PbO)_3(CrO_3)_2$ in addition; the conditions under which each of these salts would be formed were also given.

Now what are the facts Those who have to do with the chemistry of lead have been trying for years to discover the conditions under which a definite chromate of lead could be produced. Several methods of analysis have been published based on the precipitation of chromate of lead, but the conditions to be observed are many, and a slight variation from any one of them is fatal to accuracy. For these reasons the great majority of chemists have never adopted a chromate method for estimating lead.

Further investigation of the text-books showed important differences among the various authors in their manner of writing a great many reactions. Yet each gave his own idea without comment, leaving the reader to infer that no doubt exists as to its accuracy.

The writing of a good book is a difficult task and perfection is not to be expected; but why not reduce the number of imperfections to a minimum. Would it not be better, in the case of lead chromate, for example, to say that a basic chromate is produced, and that its composition varies with conditions not easily controlled. A reaction could be given, but always with an explanation to the effect that a different reaction might occur if the concentration, temperature, or some other condition were changed.

It would not be a poor idea for every man who writes a book, first to read Boyle's "Skeptical Chymist," and particularly that part wherein Boyle pleads with "those who are addicted to chymistry" to make no statements of which they are not sure. The application of this rule would materially reduce the volume of writing, but would add enough to its quality to more than compensate for the loss in quantity.

"The prophet that hath a dream, let him tell a dream; and he that hath the law, let him speak the law faithfully."

Golden, Colo. JOHN C. BAILAR.

Swedish Water Power Development.—It is estimated that the water power in Sweden increased in 1911 about 80,000 hp, aggregating at the close of the year 640,000 hp.

The Action of Electro-Mechanical Forces on the Bath of Induction Furnaces.

By Magnus Unger

The electro-mechanical forces that act upon the bath of induction furnaces are of considerable magnitude, and as a thorough understanding of the character is of importance from a designing as well as from an operating standpoint, a study of the subject may be of interest.

For a better analysis of these forces we may divide them in two classes:

1. The mutual attraction of current carrying elements within the bath, similar to the attraction of two parallel conductors carrying current in the same direction.

2. The repelling force between the bath (secondary winding) and the primary winding, similar to the repelling force between two parallel conductors carrying current in opposite direction.

Pinch Effect.

The first mentioned force has previously been fully explained by Dr. E. F. Northrup and Dr. Carl Hering and is generally referred to as the "pinch phenomenon" or "pinch effect." I would particularly call attention to Dr. Hering's paper on the subject "The Working Limit in Electric Furnaces Due to the Pinch Phenomena" (Trans. American Electro-Chemical Soc., Vol. XV, 1909; this journal, Vol. VII, p. 266, 1909).

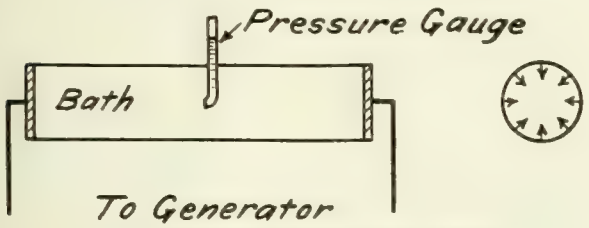

FIG. 1.—MEASUREMENT OF PINCH EFFECT.

The attractive force acting upon each current carrying element is directed so that the effect is to contract or squeeze the bath. The pressure, which is highest at the center of the bath, may be measured by suitable means as indicated in Fig. 1. Dr. Northrup gives the following formula for the pressure at the center of a bath having circular cross section:

$$P = \frac{I^2}{97.854\,S}$$

P is the pressure in grams per sq. cm.

I is the current in amperes.

S is the cross-section in sq. cm.

Although this formula is strictly correct only for conductors of circular cross section, no great error is made in applying it to conductors of square section, and it can thus be used for practical conditions such as they exist in induction furnaces.

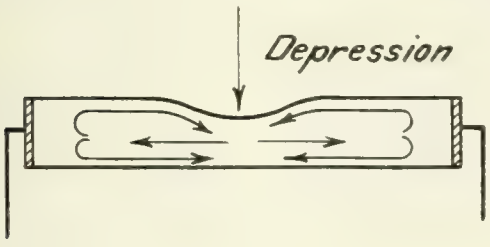

FIG. 2.—CIRCULATION OF BATH.

When current is sent through a liquid conductor of uniform section, the pinch effect will cause the liquid to be under a certain pressure, but there is no force to cause a circulation. If now for some reason or other the section of the conductor is reduced in some spot, as, for example, through a piece of floating brick, the pressure at this place, as can be seen from the above formula, will increase. The pressure at the center of the reduced area is thus larger than that outside, the effect of which is that the liquid is squeezed out horizontally in both directions from the center of the reduced area. A circulation as indicated in Fig. 2 is then the result.

In observing the circulation on top of the bath, it gives one the impression as if the liquid were sucked in under the brick. If the current is increased, this suction will also increase, and the level of the bath, where the original contraction was, will lower itself. As the current is further increased, a limit is reached when the liquid is squirted out from the center of the contracted area faster than it can return, and the result is a break in the circuit. If the liquid is sufficiently fluid, the circuit will continue to close and open some time until finally freezing occurs.

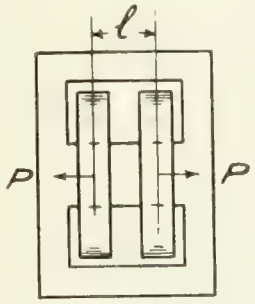

FIG. 3.—SHELL TRANSFORMER.

In the paper already referred to, a formula is developed by means of which the critical current values for the pinch effect in a liquid conductor may be calculated approximately. It is shown that the deeper the bath and the higher the specific gravity of the liquid the larger is the critical current value.

It is evident that the pinch effect is inherent with induction furnaces. As it is impossible to maintain an absolutely uniform section of the bath even in the simple design where the crucible is annular, the pinch effect will cause circulation of the bath, and the compressing effect is, of course, present whether the section of the bath is uniform or not. From a metallurgical standpoint, these features, circulation and compression, are, of course, very valuable.

Experience has shown that the pinch phenomena does not cause any difficulties in the operation of large induction furnaces as used in the steel industry. In this case the currents used are far below the critical value. However, the pinch effect makes it impossible to operate furnaces having a bath of very low specific gravity or of very low specific resistance such as aluminum and copper.

Centrifugal Effect.

The effect of the repelling force between the bath and the primary winding of an induction furnace resembles in many respects the effect that the centrifugal force caused by rotating the circular bath on its axis would have. It may therefore perhaps be proper to refer to this force as the "centrifugal force" and we may then also use the expression "centrifugal phenomenon" and "centrifugal effect."

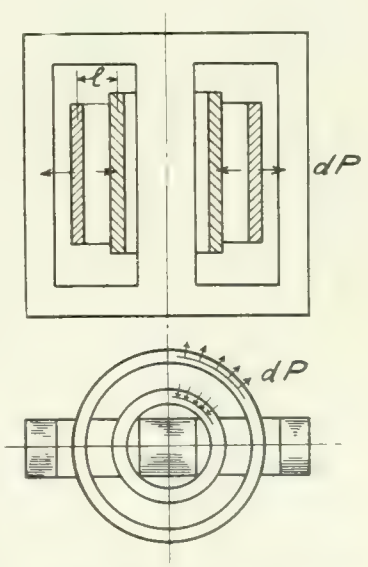

FIG. 4.—[illegible]

In an interesting paper by Dr. C. P. Steinmetz on "Mechanical Forces in Magnetic Fields" (Trans. A. I. E. E., Vol. XXIX, 1910) the theory and calculation of forces between transformer windings are given. The same reasoning may be applied to induction furnaces when it is considered that an induction furnace is theoretically equivalent to a transformer with a short-circuited secondary.

Mechanical forces will appear where magnetic fields act on current carrying conductors, as between the primary and secondary coils of a transformer. These forces are proportional to the strength of the field and current. In case of transformers the field in question is the stray field, that is, the field that does not follow the core but passes between the primary

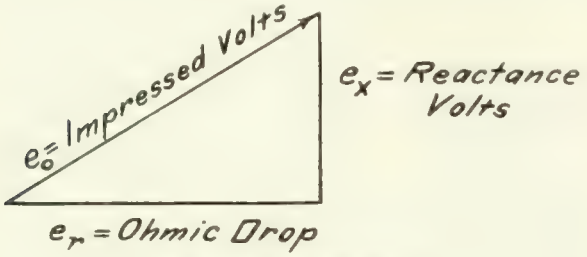

FIG. 5.—VECTOR DIAGRAM.

and secondary coils. If the secondary winding of a transformer is short-circuited and voltage is applied to the primary, no magnetic flux will pass through the secondary winding, provided that the voltage drop due to the ohmic resistance of the windings is so small that it can be neglected. In this case, therefore, the total flux passes between the primary and secondary coils. Theoretically the stray flux is caused by the reactance component of the impressed voltage. The total mechanical force which is then exerted on the winding as repulsion may be calculated from the formula:

$$P = \frac{8100\, e_x i_o l}{f}$$

P is the repulsion in grams.

e_x is the reactance component of the primary voltage.

i_o is the primary current.

f is the frequency in cycles per second

l is the distance in cm. between the coils plus half the thickness of each coil.

In transformers the voltage component due to the ohmic drop is usually so small that it can be neglected and in that case $e_x = e_o$, the impressed voltage. In induction furnaces the ohmic drop is not negligible, as the heating of the charge and the operation of the furnace is based on the secondary winding or bath having a high resistance. Referring to Fig. 5, it will be seen that e_x can easily be calculated if e_o and the primary power factor are given:

$$e_x = e_o \sqrt{1 - (\text{power factor})^2}$$

The formula for the repelling force as given above may be applied equally as well to the shell-type transformer as shown in Fig. 3 as to the core type shown in Fig. 4. In the former

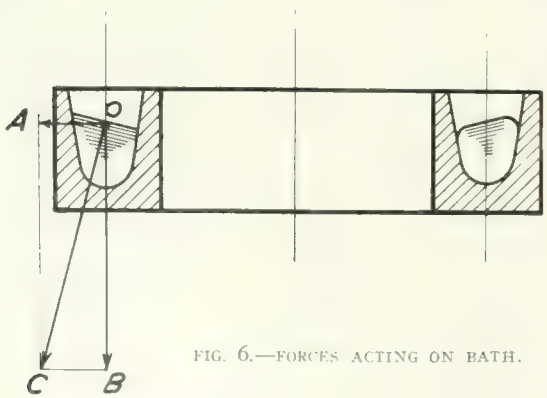

FIG. 6.—FORCES ACTING ON BATH.

construction there is actually a tendency to move the coils apart, while in the core type there is no such tendency provided that the coils are perfectly concentric. In the shell-type transformer the repelling forces on the individual current carrying conductors are all in the same direction and their algebraic sum equals P in the above formula. In case of core-type transformers these infinitesimal forces are not parallel, but are all directed radially from the center of the coils. The algebraic sum of these forces is, however, equal to "P" in the above formula. In case of core-type transformers, therefore, the effect of the repelling force is to expand the outside and to contact the inside coil.

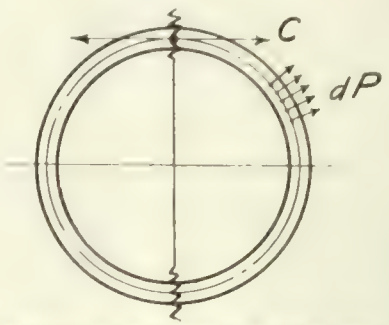

FIG. 7.—FORCES ACTING ON SINGLE-RING FURNACE.

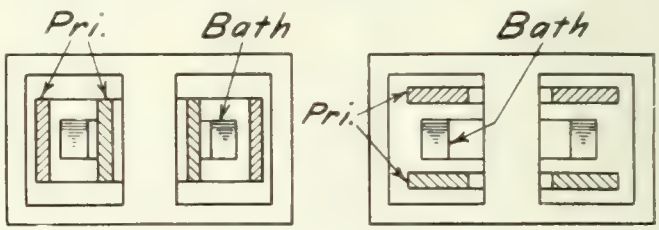
The repelling force acting upon the bath of a single-ring induction furnace is of the same nature as the force on the outside coil of a core-type transformer, that is, the centrifugal effect is present. If we disregard the pinch phenomenon, it is then evident that two mechanical forces act upon each element of the bath, the gravity (OB) and the centrifugal force (OA) as shown in Fig. 6. The level of the bath must be perpendicular to the resultant force (OC), that is, it will be inclined to the horizontal as shown.

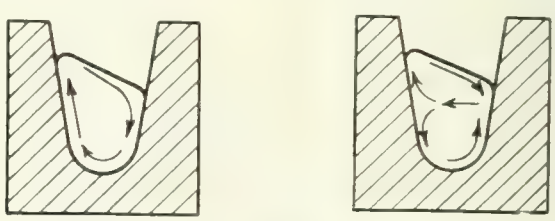
As the pinch effect tends to make the cross section of the bath circular, we should expect that the section would be as



FIGS. 8 AND 9.—DIVISION OF PRIMARY WINDINGS IN SECTIONS.

shown on the right hand side of Fig. 6. This is also exactly what has been observed in induction furnaces. That the centrifugal force may be of considerable magnitude is proven by the fact that in a large Kjellin furnace when operating at full load the level of the bath is inclined about 30 deg. to the horizontal.

While the centrifugal force throws the liquid bath against the outer wall of the crucible, and thus tends to force out enclosed gases, there is no tendency to break the circuit. Such tendency is, however, present in case of a solid secondary ring such as



FIGS. 10 AND 11.—CIRCULATION OF BATH.

is used in starting the furnace. The force (see Fig. 7) which tries to tear the ring apart can easily be calculated and is equal:

$$C = \frac{P}{2\pi}$$

With P obtained from the previous formula, the value of C will be given in grams.

While this force is far too small to break the ring at normal temperatures, it may be high enough to do so at higher temperatures when the tensile strength of the material in question gets low. Actual experience has shown that starting rings

may break open shortly before they get liquid, leaving an absolutely clear break such as is obtained when broken under ordinary tension. While this phenomenon may have been ascribed to the pinch effect, it is undoubtedly due to the centrifugal effect.

The centrifugal force causes a very marked circulation of the bath. This circulation takes place in planes at right angles to the direction of the bath and has been explained as follows:

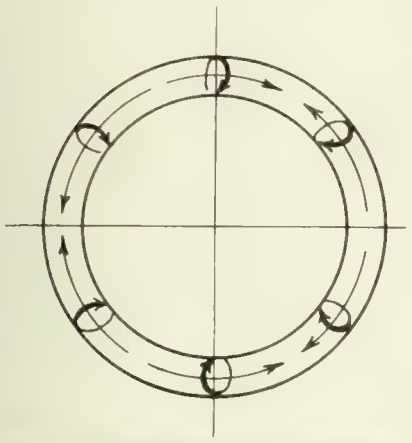


FIG. 12.—CIRCULATION IN SINGLE-RING KJELLIN FURNACE.

The metal at the surface of the bath has a tendency to cool and thus gets heavier than the interior metal. Due to the slanting level of the bath the heavier metal will sink down along the top of the bath and the inside wall of the crucible, thus setting up a circulation as indicated in Fig. 10.

It seems, however, that this circulation can be explained as caused directly by the centrifugal force as follows:

The repelling force between two current carrying conductors is stronger the shorter the distance between the conductors. The force on the current carrying elements along the inside wall of the crucible is therefore stronger than on those further out and the result is a circulation as indicated in Fig. 11.

The circulation caused by the centrifugal force may be so violent as to wear and seriously shorten the life of the crucible lining. This difficulty can, however, be avoided by using suitable designs, as the formulas available allow the operation of a furnace to be well determined.

From the previous discussion it is evident that by dividing up the primary winding in sections, as shown in Figs. 8 and 9, the effect of the centrifugal force may practically be eliminated, or by choosing other locations the centrifugal effect may be calculated to give a mild, desirable circulation of the bath. In this manner the trouble from breaking of the starting ring will also be reduced or fully overcome. This trouble may also be reduced by decreasing the power when the ring gets up to a high temperature.

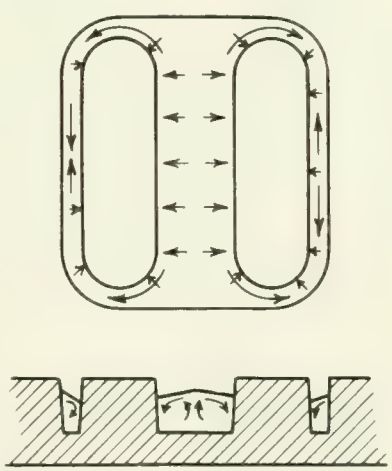

FIG. 13.—CIRCULATION IN ROECHLING RODENHAUSER FURNACE.

The circulation is liable to be more pronounced in large furnaces, and to overcome this difficulty the furnaces designed by Frick and by Hiorth have sections of the primary winding located above and below the bath.

Combined Effect.

The pinch, as well as the centrifugal force, exerts a compressive effect upon the bath, and which is of great value in tending to free it from enclosed gases, and thus give a homogeneous product.

The circulation set up in the bath by the magnetic forces, as explained, is very desirable in order to obtain a uniform product.

The circulation in the bath of a single-ring Kjellin furnace is indicated in Fig. 12 and that of a single phase combined induction and resistance furnace (R & R type) is shown in Fig. 13.

Steel?

BY J. W. RICHARDS

"Call a spade a spade"; but beware how you call it a *steel* spade!

We are getting nearer and nearer to an inevitable *impasse*, as to what is meant or what shall be meant when we say "steel." Let us briefly review the past and the present meanings of the word, in order that we may intelligently decide what its future, fixed and definite, meaning ought to be.

Thousands of years ago, Tubal Cain made iron directly from iron ore, and undoubtedly he or someone soon after him, left iron in the fire till it became carbonized to steel. The original product from the ore was soft wrought iron, not holding a cutting-edge long, and not capable of being hardened or tempered. The finer material made from soft iron could be hardened and tempered, and held a cutting-edge; from whence came the famed blades of Damascus and Toledo, the Malay creese and the Saracen scimeter. Tradition says that the fine temper of the Damascus blades was due to the virtues of a famous spring in which the hardening was performed; the Japanese swordsmith put on a ceremonial robe when he tempered his Lord's sword, and the true Samurai parted with every earthly possession before suffering separation from his "honorable" weapon. Such sentimental, ornamental, fine, delicate, superlative stuff was the ancient steel, treasured by man and appreciated by the gods.

In the fifteenth century, comparatively recently in the history of siderurgical art, the "high furnaces" of Germany began turning out a new product, a fluid impure iron, so far removed in nature from iron or steel as to be considered at first a waste and undesirable material. It was fusible at a white heat, whereas no one had before melted iron or steel; it was hard, brittle, incapable of being hammered or forged, softened or tempered. This "Roheisen" was called by our forefathers "cast iron," because it was the first iron they had even seen cast, or capable of being cast. We know the material somewhat better than they, we know its characteristics to be due to 2.2 per cent or over of carbon content, and we know how to soften it somewhat when we want a cheap semi-malleable metal-casting. This material, however, the product of the blast furnace or a similar furnace, manufactured directly from iron ore, we call "pig iron," and when re-melted, "cast iron." There are no two opinions as to what this material is, what we call it, and what we ought to continue to call it.

Passing on, however, from the 15th century, we find Huntsman, in the 18th century, melting steel and making "cast steel," so called because it was the first appearance of fluid steel, cast into moulds, in the industry. It was very well and appropriately named; it had the identical qualities of the best steel which had never been fused, except that the fusion, if carefully done, left it improved in quality. Attempts were made to melt and cast soft wrought iron, but they did not then succeed. What they might have called the product, had they succeeded, it is useless to speculate upon.

Early in the 19th century considerable steel was made in the puddling furnace, the puddling operation being stopped before the stage of soft wrought iron had been reached. This cheap steel was variously called puddled-steel, wrought-steel, and later weld-steel. It was extinguished as a commercial product by the advent of Bessemer steel.

In 1855 Bessemer discovered his cheap way of making steel blowing cast-iron to melted soft iron, and then re-carburizing to the desired quality of steel. He did not make an ultimate product so low in carbon that it would not harden and temper, and therefore Bessemer steel took its place in commerce without raising any question of nomenclature; the product was simply cast fluid steel of the ordinary definition.

In 1862 the Siemens-Martin furnace came on the stage, producing a de-carburized molten material which was practically pure soft iron, but re-carburizing it to steel in the ordinary sense of the word as an ultimate product. Later, improvements in the re-carburizing and de-oxidizing material added made it possible to turn out a low-carbon product properly de-oxidized, and the open-hearth steel furnace then commenced to put on the market a new product, one never seen before in commerce, a low-carbon cast material resembling open-hearth steel in manufacture and uses excepting that it was not capable of being hardened and tempered. In fact, it soon found uses, such as for boiler plates, where hardening and tempering were no longer in question, but where strength and uniformity were the main *desiderata*. Then a merry war of nomenclature commenced. The manufacturers wanted to call it steel, because of the superior qualities associated with that name, and since they made it in the same furnace, from the same materials, in the same way, as ordinary carbon steel which did harden, they saw no impropriety in selling it as steel—soft steel, mild steel or dead-soft steel. The users, in general, accepted these terms. Objections were made by purists in classification, who pointed out that steel, as so far understood in the history of the art, must contain enough carbon to usefully harden and temper: "soft steel" did not answer these requirements, and therefore was not steel. The Germans recognized most clearly this violence to the old classification, and steadfastly and consistently refused to officially recognize the new product as steel: the German tariff laws refer to it as "fluss-eisen" or "flowed-iron," the English equivalent being "ingot iron."

After fifty years of discussion the commercial, scientific and even the official world has about settled upon calling this soft, cast material "steel," we may regard it as *fait accompli*, and accept what appears to be the inevitable. I believe there is no longer any protest against this, as practically everybody is now agreed. Let us put it down then, as ultimately settled, that the low-carbon product of the steel melting furnace, incapable of usefully hardening or tempering is and should continue to be called "steel."

Starting from this standpoint, what shall we now give as a scientific or accurate definition of steel? As the case now stands we have to make a hybrid definition, to fit an anomalous situation, *viz.*, steel is that form of usefully malleable iron which contains sufficient carbon to usefully harden and temper (old material steel, from the commencement of the industry), and *also any* usefully malleable product of the steel-melting furnace which may contain less carbon than this amount. We have here a definition which describes the facts, as to what is now called steel, but which refuses to fit into a scientific classification of iron and steel products.

In this dilemma, what are we to do? Let things go, says one, because the definition fits the facts; but this is simply leaving the matter is an unsatisfactory condition as far as man's instinct to arrange and classify is concerned. Make a new definition of steel, says another, call everything made in a *steel-melting* furnace steel, and cut out everything else. Now, here are two radical propositions, the first unsatisfactory to our rooted instincts of orderly classification, the second so unjust and arbitrary as to deserve a protest from every lover of fair-play and consistency.

It appears to me that the scope of the term steel has been gradually widening, and that in the future it will become still more comprehensive. If we adopt a principle of classification which narrows the scope of the term, we will not only be doing injustice but will be working against the tendency of the times. It is therefore evident that the best principle of classification to adopt is that which broadens the term until it covers, as simply as possible, all that the term can properly be extended to cover.

Our former classification has broken down. We can no longer set up ability to harden and temper as the essential characteristic of steel. Neither should we set up the criterion of having been produced in the fluid state in a steel-melting furnace, thus barring out all steel of plastic origin—the historic steels. Furthermore, it is a false principle of classification to use the method of manufacture as a basis; the materials should be classified on properties ascertainable fromthe materials themselves, and in no manner on their past history.

At this point, the writer proposes that *malleability*, useful malleability, be made the criterion of classification: that all iron be divided into (1) the brittle, not usefully malleable material, cast iron, and (2) the usefully malleable material, steel. The classification is thus based upon a most valuable physical and commercial property which is readily ascertainable. It allows the term steel to include everything that is now known as steel, and, for the purposes of a proper and scientific classification, based on a physical property, includes in it one material not now called steel.

Wrought iron is not pure iron, but contains small quantities of carbon, phosphorus, sulphur, etc., with some intermingled slag. Dead-soft steel, of lowest carbon content producible in the steel melting furnaces, is of similar chemical composition, and nearly free from intermingled slag. The two materials have nearly identical physical properties and uses, one is often sold for the other, and one is often used indifferently for the other, *e. g.*, black plates for tin-plate. In a broad classification no violence is done by putting these two materials in the same large class. Call that class steel, and its intrinsic characteristic useful malleability, and the end in view is attained—a strictly scientific and practical classification, based on ascertainable properties.

I, therefore, propose that "Steel" be the generic name for all varieties of usefully malleable iron, and if doubt exists as to whether the material is usefully malleable, that the containing of less than 2.2 per cent of carbon be the supplementary criterion. The term would then include the following materials: Of plastic origin (welded together), wrought iron, puddled steel, blister steel, cemented bar, single-shear steel, double-shear steel; of fluid origin (cast from the fluid state) ingot iron, mites castings, dead-soft steel, mild steel, carbon steel, alloy steels.

The broad classification proposed would simply be:

Commercial Iron	
Usefully malleable. (Carbon under 2.2%)	Not usefully malleable. (Carbon over 2.2%)
Steel.	Cast Iron.

The effect of altitude on roasting is mentioned by Pearse in Bulletin No. 90, I. M. M. He states that at an altitude of 13,000 ft., with 52 per cent oxygen in the atmosphere, the effect on Bruckner roasters was to reduce their capacity to about 33 per cent: in other words, about three times the number of Bruckner furnaces would have to be installed at the altitude given than would be necessary at sea level in order to supply a blast furnace of given capacity. At 15,000 ft., with 44.5 per cent oxygen in the atmosphere, the roasting value was reduced to about 25 per cent.

The introduction of the tube mill in metallurgy is credited by Henry Hanson in a paper read before the Canadian Mining Institute, to Dr. Ludwig Diehl, who was metallurgist for the London Hamburg Gold Recovery Company, and who made a success of the Hannan Brown mill in Australia. The first mill of this type was installed by Dr. Diehl at the Hannan Star Mine, Kalgoorlie, Western Australia. Since then the tube mill has found a place of increasing importance in the metallurgy of gold and silver ores.

The Evaporative Capacity of Lead-Lined Copper Coils.

A Record of Three Runs from Evaporation Practice with Some General Practical Conclusions on Evaporation.

By B. Viola, M. E.

Member American Society of Mechanical Engineers.

As I have mentioned in former articles, only lead coils are suitable as a heating surface for the evaporation of certain acids, since they are acid-proof to a certain extent. However, as they are not very strong mechanically, they do not last very long, they lose soon their original shape and finally become absolutely useless for the purpose for which they are intended.

To get a stronger and longer lasting heating surface, lead-lined copper coils may be used instead. They have proved very effective in practice. They last at least three times as long as pure hard-lead coils. The vacuum pan in this case is mostly a single-effect, of the construction shown in Figures 41 and 43 in one of my former articles (this journal, Vol. IX, page 349, July, 1911).

It would be a very hazardous thing to assume with positiveness in advance a certain value of the heat transmission coefficient for any heating coil, because it always depends on the thickness of the liquor, on the diameter and the length of the heating coil, and on the effective temperature of the heating steam.

Even when using the same apparatus different results are obtained with the same heating coil, if there are any differences in the condition of the scales on the surface, and these are hard to control. Further we know from the readings of our measuring instruments that we do not get exactly the same records all the time. Therefore, when we speak of the heat transmission coefficient, we always mean approximate or mean values. Such variations as occur in practice I will illustrate by a few records of runs, which will clearly prove the correctness of my assertions.

First Run.

Thirteen thousand two hundred and eighty five kgs. citric acid liquor at 8½ deg. B and 43 deg. C. were concentrated to 32 deg. B. at an average boiling temperature of 145 deg F. = 62.78 deg. C., as shown on recording chart Fig. 58, with a lead-lined copper-coil heating surface of 10.66 square meters, consisting of two lead-lined copper coils, 75 mm diameter of copper with 5 mm lead lining, so that the outside diameter is 85 millimeters, each coil being 20 meters long. Then according to formula (7) (this journal, January issue, 1912, page 32) $W = 9631$ kgs. of water have to be evaporated.

This run was finished in 12 hours or 802.66 kgs. were evaporated per hour. This gives an evaporation of 75.3 kgs. per square meter an hour.

According to equations (2) and (6).

$$W = \frac{HC\,(t_2 - t_1)}{Q_t - t_0} = 75.3$$

where

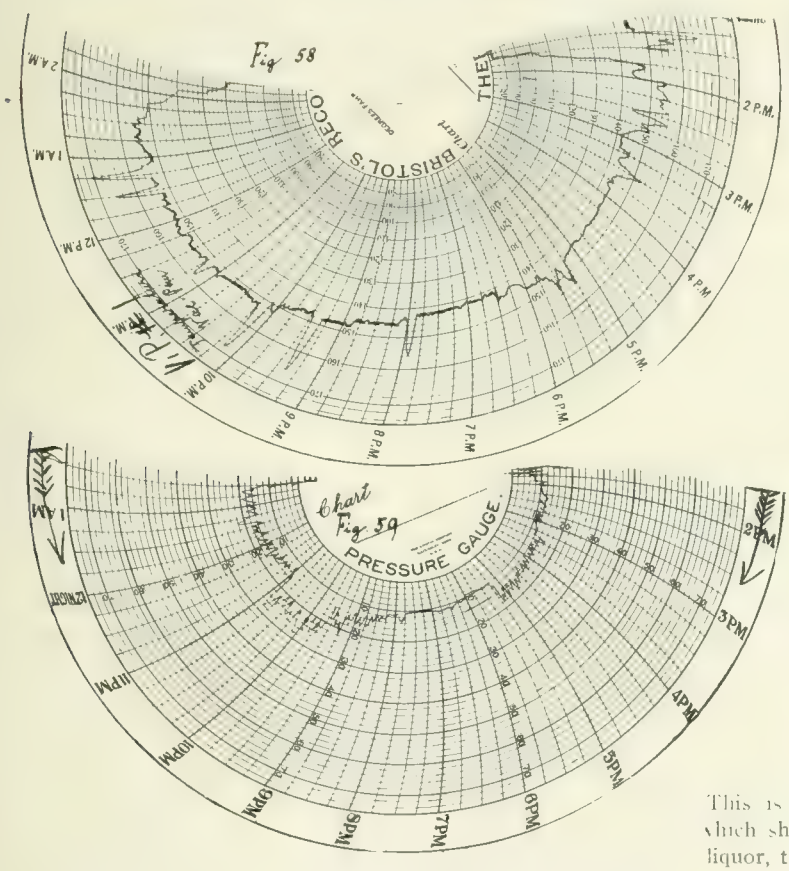
$H = 1$.

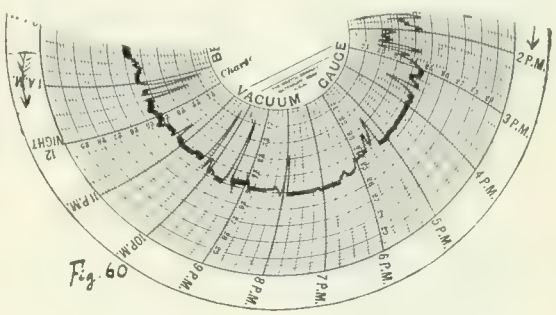
$t_2 = 102.78$ deg. C. temperature of heating steam.

$t_1 = 62.78$ deg. C. temperature of boiling liquor.

$t_0 = 43.0$ deg. C. original temperature of liquor.

Hence C. = 1107 calories per square meter and hour. This is the coefficient of heat transmission corresponding to an hourly evaporation of 75.3 kgs. of water per square meter and hour under the conditions of the run.





RECORD CHARTS OF FIRST RUN.

FIG. 58.—BOILING TEMPERATURE.

FIG. 59.—STEAM PRESSURE.

FIG. 60.—VACUUM.

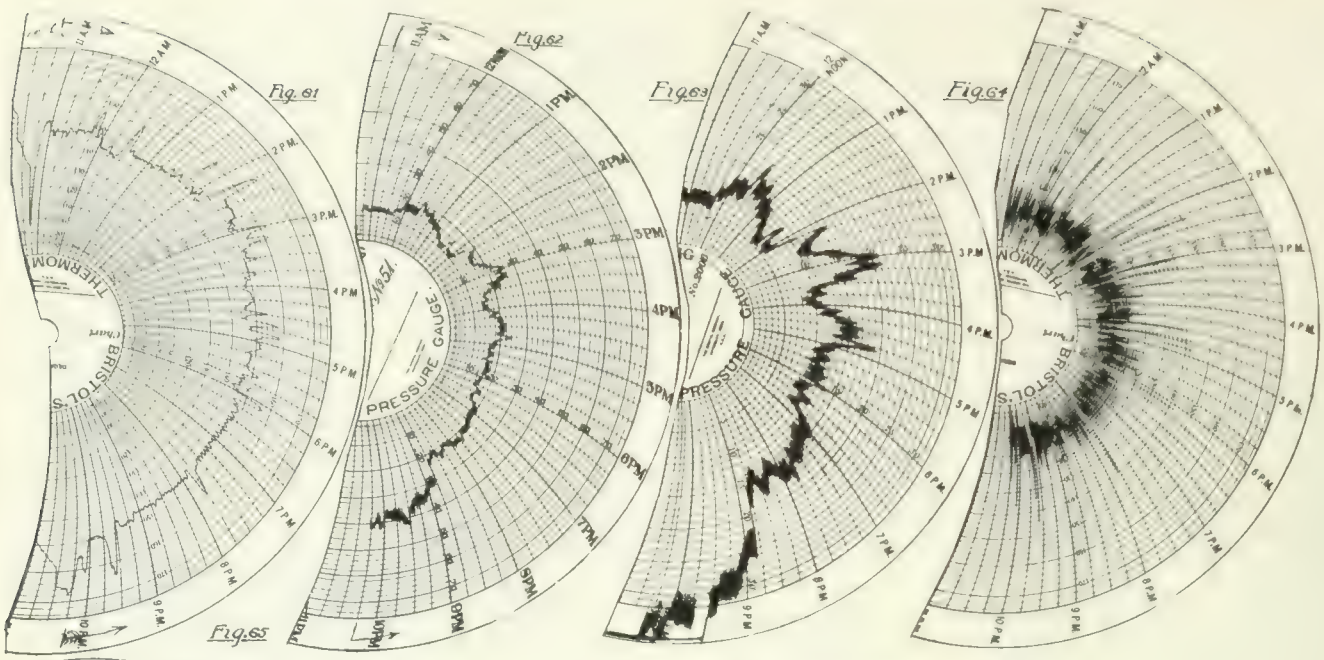
The quantity of steam and the calories needed for the evaporation can be easily calculated from the equations (4) and (25) of the previous article quoted above.

It is very interesting and instructive to follow closely the conditions during the evaporation. This is possible by means of reliable recording instruments which show the steam pressure, the boiler temperature of the liquor, the vacuum at which the evaporation is carried out, etc.

For the evaporating process under discussion running from 1.30 p. m. to 1.30 a. m., Fig. 59 shows the steam pressure (which determines directly its temperature). Fig. 58 shows the boiling temperature in the vacuum pan during the same period, and Fig. 60 the vacuum under which the process was carried out.

It is very astonishing to see on the temperature chart 58 the many variations of the boiling temperatures. However, when we compare it with Fig. 60 (the vacuum chart), we find the explanation.

This single effect was a part of a group of vacuum pans, all connected to the same vacuum pump. Now, for instance, at 5.15, 9.30, 10.15 p. m., etc., the vacuum went down because some of the other vacuum pans were freshly charged and at this time



RECORD CHARTS OF EVAPORATION.

FIG. 61.—TEMPERATURES OF BOILING LIQUOR.

FIG. 62.—PRESSURE OF HEATING STEAM.

FIG. 63.—PRESSURE IN EXHAUST STEAM.

FIG. 64.—TEMPERATURE OF CONDENSE WATER.

FIG. 65.—VACUUM.

all the air had to be removed from these pans. The vacuum pump, being thus suddenly overloaded, was not able to keep up the high vacuum so that at such times the vacuum fell off a few inches until all the air was drawn off. This is a direct demonstration of the fact that the lower the vacuum the higher the boiling temperature and a direct explanation of the reason why in a multiple effect the first body has the lowest vacuum and the highest boiling temperature and reversely the last body the highest vacuum and lowest boiling point.

Second Run.

In a later run with the same single effect and the same two lead-lined copper heating coils 11,039 kgs. of 9 deg. B. liquor at 31 deg. C. were concentrated to 3091 kgs. of 31 deg. B. at 148 deg. F. = 64.45 deg. C. average boiling temperature in 10.4 hours.

$W = W_w - W_e$ 11,039 3091 7948 kgs.

By taking into consideration, that

t_1 = 108.80 deg. C. (Fig. 61)

$t_1 = 64.45$ deg. C.

$t_0 = 31.0$ deg. C.

we find the heat transmission coefficient to be C. = 876 calories per square meter and hour and the evaporation per square meter and hour to be 65.38 kgs. water.

Comparison with the first run will show that the same apparatus under nearly the same conditions has evaporated 10 kgs. water less per square meter and hour (65.38 instead of 75.3 kgs.). Accordingly the heat transmission coefficient was lower (876 instead of 1107 calories per square meter and hour). This run No. II was made about six weeks after the run first mentioned above. There is no doubt that the heating surface was very much more coated with scale. Naturally such conditions should always be avoided and the endeavor should be to keep the heating surfaces as clean as possible.

This second evaporation process lasted from 10.40 a. m. till 10.15 p. m. and all the records can be seen on charts Fig. 61 (temperature of the boiling liquor), Fig. 62 (heating steam pressure which determines the temperature of the heating steam), Fig. 63 (exhaust steam pressure which determines the temperature of the exhaust of the heating steam), Fig. 64 (the temperature of the condense water), and Fig. 65 (the vacuum under which the process was carried out).

Third Run.

I will now discuss the concentration of three different liquors, all of which have originally different densities and are to be concentrated to the same density.

The same single effect was used as before, equipped with all controlling gauges. But in contradistinction to the former runs, in the third run only this vacuum pan was connected to the vacuum pump and condenser. The time of evaporation was from 8.15 a. m. till 12.20 p. m. or 4 hours 5 minutes. The conditions of the liquors were as follows:

	—Thin Liquor.—			—Concentrated Liquor.—		
					t_1 — C.°	
No.	B.°	Temp. C.° t_0	Quantity kgs.	B.°	Boiling Temp.	Quantity kgs.
1	6½	20	1936.64	41	55.55	381.52
2	21½	56	1829.33	41	55.55	821.37
3	26½	56	2809.8	41	55.55	1573.5

According to our formula:

$W = W_w - W_e$, the following quantities of water were evaporated:

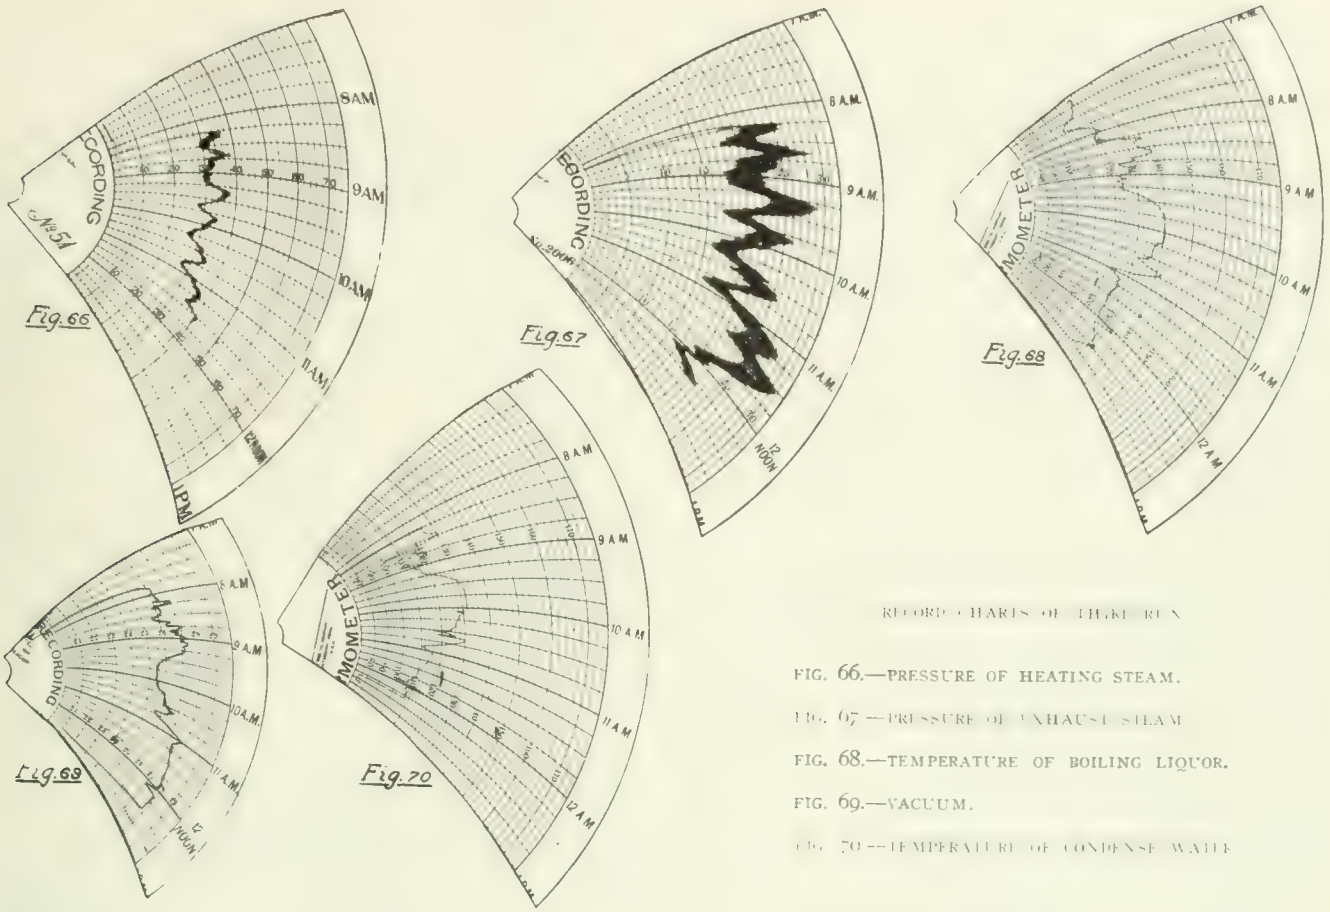
(1) 1936.64 — 381.52 = 1555.12 kgs.

(2) 1829.33 — 821.37 = 1007.96 kgs.

(3) 2809.80 — 1573.50 = 1236.30 kgs.

As can be seen on each recording chart, the time of evaporation was 4 hours and 5 minutes. The evaporated water per square meter and hour was 86.69 kgs.

From our formula the heat transmission coefficient C. can be found, taking into consideration the average pressure of the heating steam (Fig. 62).



RECORD CHARTS OF THE TEST RUN

FIG. 66.—PRESSURE OF HEATING STEAM.

FIG. 67.—PRESSURE OF EXHAUST STEAM.

FIG. 68.—TEMPERATURE OF BOILING LIQUOR.

FIG. 69.—VACUUM.

FIG. 70.—TEMPERATURE OF CONDENSE WATER.

= 33 lb. = 250 deg. F. = 124.44 deg. C.

and the average result is

C = 738 calories per square meter and hour.

By comparison with the two former runs, it will be seen that although in the third run the coefficient of heat transmission was lower, yet the evaporated quantity per square meter and hour was much larger than in the two previous cases.

The reason is simply that the evaporating process was not disturbed by any changes made with other vacuum pans. Such changes cannot be avoided of course, with a crowded vacuum plant, where many pans are served by one condenser and one vacuum pump. This result shows plainly the disadvantages of such a plant *and is a convincing proof in favor of the one-vacuum-pan, one-condenser, one-vacuum-pump system.*

Fig. 67 shows an ideal exhaust recording chart, where the variations correspond perfectly to the variations of the heating-steam pressure.

The variations of the boiling temperature can be seen in Fig. 68. The variations are due mainly to the temperatures of the different liquors which are drawn into the vacuum pan. Toward the end of the concentration the temperature is kept well uniform.

Fig. 69, the recording chart of the vacuum, under which the evaporation takes place, shows very clearly the close connection between the boiling temperature and vacuum. The higher the vacuum can be kept, the lower will be the boiling point, and vice-versa. This point has to be taken into consideration in connection with the quantity of cooling water.

Comparing further the boiling temperature with the temperature of the condense water (Fig. 70) we see the advantages of the method of maintaining the temperature difference between the boiling point in the last body of a vacuum plant and the condense water always at 10 deg. to 15 deg. even if the temperature is not kept uniformly. With this subject, however, I will deal in greater detail in my next articles about condensation.

The Experimental Ore Dressing and Metallurgical Plant of the Colorado School of Mines.

By Victor C. Alderson

President, Colorado School of Mines.

The opening of the experimental ore dressing and metallurgical plant at the Colorado School of Mines is an epoch-making event in the history of mining in Colorado comparable with the discovery of gold on Cherry Creek in 1859, the erection of Senator Hill's smeltery at Black Hawk in 1867, the successive regeneration of Leadville, the discovery of Cripple Creek, or the application of cyanide to low-grade gold and silver ores.

Commercial ore testing plants are not unknown. They have been established as adjuncts to mining machinery houses; they have been promoted by private capital; they have generally been satisfactory and have benefited the mining industry. The plant at the School of Mines will in no way compete with these private establishments. Rather will it increase their business by calling the attention of mining men to the necessity of a careful preliminary investigation of their ore before they erect a costly mill.

The Need of an Experimental Plant.

The problems that confront the mining man in the treatment of his ore are greater than those confronting him in raising his ore to the surface, *i. e.*, the metallurgical are more serious than the mining problems. The passing of the high-grade ores, except in lucky finds, has brought the industry to the point where low-grade ores must be treated at a profit or the mining industry must go into eclipse.

Each camp, each mine, and even each vein has its characteristic problem. In Boulder county, Colorado, the problem is not only to concentrate the tungsten ores, but at the same time to save the gold content. The low-grade ores of Clear Creek

and Gilpin counties need cheap local treatment. Leadville faces the problem of handling zinc-carbonate ores which carry less than 20 per cent of zinc. The problem of Cripple Creek is to treat low-grade telluride ores by an adaptation of the cyanide process without preliminary roasting. It is estimated that $100,000,000 is lost every year by inefficient methods of ore treatment. This loss should be stopped.

The greatest need of the mining industry in Colorado is a more thorough knowledge of ore treatment, more technical skill, greater refinement in mill operation, besides more careful economy and business efficiency. The time is past when the average mine can withstand waste, extravagance and loose management. The mine operator must learn that every dollar per ton saved in operation is equivalent to an increase of a dollar per ton in the value of his ore. He must learn just the character of mill which must be erected to treat his ore. This experimental plant will, undoubtedly, cause great economy in two lines: in the erection of mills and in the time saved in preliminary experimental work.

The Building.

The building of the experimental plant is situated on the bank of Clear Creek, a few blocks from the campus of the School. The slope of the bank is in itself sufficient to carry off water with considerable solid matter in suspension. The building is 98 by 141 ft. 8 in. on the ground floor. The frame work is of structural steel resting on concrete foundations which have been carried down to a substantial bed of gravel. The walls consist of 2½ in. of cement mortar, reinforced by "hy-rib," and are of natural cement color. The roof is of elaterite resting on a 2-in. sheathing of matched Oregon fir. The ground floor is concreted throughout and is divided into three sections of different elevations. Above the ground floor, but covering only a part of the area, are two suspended floors of reinforced concrete, supported by steel frame work. The building is well lighted and is ventilated by an easily operated monitor ventilator.

Power.

All machinery and apparatus requiring power is operated by alternating-current motors supplied with current from the School of Mines power house. For the generation of the current required, a producer-gas-power-generator unit of 80-kw capacity has been installed in the power house. This unit is of Westinghouse design throughout and consists of a bituminous suction gas producer, a vertical three-cylinder gas engine, and a direct-connected alternating-current generator.

The producer has a number of noteworthy features. The principal one, and the one which contributes so largely to its success, consists of the two distinct fire zones. This feature makes it possible to operate successfully on very low-grade fuel, and eliminates the difficulties usually arising from the tar and hydrocarbons given off and deposited during the process of gas making. Ordinary Colorado lignite coal is used. From this is produced a cool, clean gas with a heat value of from 115 to 130 B.t.u. per cubic foot. To eliminate the loss of power on account of a reduced intake pressure, a motor-driven, positive-pressure type of exhauster is used. This draws the gas from the producer and delivers it to the engine at a pressure corresponding to about 4 in. of water.

The engine is of the standard Westinghouse vertical three-cylinder type, single acting, and using a four-stroke cycle. The cylinders are 15 by 14 in. (stroke). At a speed of 257 revolutions per minute, the engine, operating on the producer gas, delivers 118 brake-hp. Compressed air is used for starting, and both engine and producer can be started readily, even though having stood idle for several days.

Direct-connected to the engine through a flanged coupling is an 80-kw, 2300-volt, three-phase, sixty-cycle generator. The current is transmitted at this voltage to the experimental plant where it is stepped down to the working voltage of 440. The installation is such that the 80-kw machine can be operated in parallel with a steam turbine in the power house. In case of an emergency all power can be supplied from the turbine alone.

Water Supply.

A concrete-lined well, 5 ft. in diameter and 25 ft. deep, has been sunk near the bank of Clear Creek. A 4 by 6-ft. tunnel, 120 ft. long, extends from the bottom of the well to a stratum of gravel under the bed of the creek. The well and tunnel have a storage capacity of 20,000 gal. The pumping outfit consists of an automatic motor-driven, submerged-type, two-stage centrifugal pump. This has a capacity of 100 gal. per minute against 50-lb. pressure, pumping into pressure storage tanks of 2500-gal. capacity. An ample supply of clear water is thus assured for all operations.

Sections.

The plant, when fully equipped, will consist of four sections or units—sampling, concentration, cyanidation, and a fourth devoted to roasting and special apparatus, such as magnetic and electrostatic separators, dry tables and flotation schemes. For general equipment the plant will contain a Curtis air compressor, a two-stage centrifugal pump, three large water supply tanks operating under air pressure, two motor-operated platform elevators, giving control over all the floors, a Ruggles-Coles dryer, ore bins, track scales, turn tables and ore cars.

The sampling section will contain the following equipment: one Vezin sampler, one Brunton sampler, a portable feed hopper, one set 12 by 20-in. Traylor rolls, one 2 by 6-in. Sturtevant roll jaw crusher, with accessories for finishing the sample such as laboratory crusher, and pulverizers, bucking board and riffles. In addition to this a complete gasoline assay furnace outfit will be installed.

The concentrating unit will consist of one 7 by 10-in. Blake crusher, one Samson crusher, one 2D Gates gyratory crusher, one set 14 by 30-in. P. & M. M. rolls, one set 12 by 24-in. P. M. M. rolls, one set triplex rolls, one 3½-ft. Huntington mill and one 3½-ft. Akron Chilean mill for regrinding, one Richards pulsator jig, one Harz jig of one compartment, one Harz jig of five compartments, one standard Card table, one No. 6 Wilfley table, one Wilfley slimer of latest design, one Johnston vanner, one Traylor vanner, one Richard pulsator classifier, one three-compartment classifier, two Callow cones, grizzlies, impact and revolving screens, sampling devices and the necessary sand pumps, elevators and concentrate driers. In addition the concentrator will contain a battery of five 850-lb. gravity stamps, equipped with amalgamating plates, Pierce amalgamator and clean-up pans. A special feature of this unit will be the installation of small-sized apparatus for the handling of small ore lots, *i. e.*, a Callow miniature ore-testing plant, a quarter-size Wilfley table and a quarter-size Card table. Through this arrangement, ore lots of any size whatever may be tested efficiently.

The cyanide section will contain one 3-ft. tube mill, one 3½ by 10-ft. Pachuca tank, one Paterson agitator, a Dorr classifier, a Dorr thickener, thickening cones, a Butters filter, one six-compartment zinc box, one lead-lined acid tank, one filter press for zinc slime, solution storage tanks and a small pebble mill. This department also will be provided with small-scale apparatus in the shape of agitators and precipitating devices.

In the fourth section provision will be made for the installation of special machinery, whereby its efficiency may be tested and comparison made with standard apparatus; for testing by roasting and magnetic or electrostatic separation, by dry tabling, and by such new processes and apparatus as may from time to time come before the metallurgical and mining public.

The Importance of Preliminary Treatment.

The proper preliminary mechanical preparation of an ore is one of the most important metallurgical problems with which we have to deal. So many factors enter into its consideration

that it becomes a very complex question. The nature of the ore, the state of aggregation of the constituents, the commercial conditions for disposal of products, and other factors have their influence.

If the ore, like the copper sulphide of Butte, is in a state of coarse aggregation, then coarse crushing with concentration beginning at the maximum size—in this case about 2 in. in diameter—is used for the double purpose of keeping the production of slime at a minimum and also producing as large a quantity of coarse concentrate for the blast furnace as practicable. In general, it is a safe rule to reduce ore only to the requisite fineness to secure satisfactory results and to avoid slime—the bane of the concentration man.

In cyanidation it may be necessary to reduce only to ¾-in. diameter in order to secure a practically complete extraction as was done in the early Mercur practice; on the other hand, it may be necessary to bring all the material to a practically impalpable powder as in the case of the all-slime treatment of silver ores. Each case presents a problem of its own, the successful solution of which means much in the subsequent treatment of the ore. In order to carry on this preliminary treatment at a minimum expense small-size equipment is installed. For a preliminary investigation on small apparatus, a mine owner may send 50 lb. On this small amount, work may be done in any one of a variety of ways, the results of which

EXPERIMENTAL ORE DRESSING AND METALLURGICAL PLANT OF COLORADO SCHOOL OF MINES

will point to more extended work, possibly on a car-load lot. By this means a mine owner may, at a minimum cost, and with the maximum amount of investigation, learn what process is best adapted to his ore and what kind of a mill to erect. This will appeal especially to the small mine owner, for it puts him on an equality with the large corporation. The wealthy mine owner can employ the best talent because he has the money to pay for it. But the School of Mines' plant will be available to everyone.

Flexibility.

A special feature, carefully considered in building the plant, is its flexibility. The installation of launders, conveyors and elevators is so arranged that any combination or variety of tests may be made. Ore may be taken from one part of the plant to any other for comparing the effect and value of different screens, classifiers or concentrators working upon the same material and under similar conditions. This is an important feature because it will enable a wide range of work to be done. If there is any solution whatever to the problem of the reduction of rebellious ores it certainly can be discovered by means of the facilities of this plant.

Self-Salting.

The utmost pains have been taken to avoid self-salting. This precaution is especially necessary when successive tests follow each other closely. To avoid this danger all launders are designed to be easily flushed; compressed air is installed for cleaning, and all obstructions to the free passage of ore are removed.

Educational Features.

Although the location of the Colorado School of Mines is an ideal one, and it is possible to see practical ore dressing and metallurgical plants at any time, this fact does not make the need of an experimental plant at the School any less imperative. The School takes advantage of its location by requiring numerous carefully conducted inspection trips, in which students, in squads of small numbers, are required to make detailed studies of processes in operation and to hand in reports of such studies. By a series of outlines, each devoted to some particular practice, care is taken that no detail of importance is overlooked. This method produces excellent results, is carried out as fully as possible, is of immense value, and is a very important part of the curriculum. Visits of inspection, however, are necessarily limited in time, and admit only a cursory study of operations. Furthermore, it is difficult, if not impossible, to study the mechanism of a machine while it is in motion. What is needed is a plant with type machines which can be studied under all conditions, and which can be adjusted so as to answer the requirements of experimental work.

The fact remains that the best results these inspection trips can accomplish is to bring about the knowledge of the particular practice, good or bad, at the plant visited, without the opportunity of learning how or why the practice produces the results obtained. In the study of concentration, for example, breakers are run at a certain speed, with jaws at some fixed distance and with the feed regular or irregular. What should be done is to show how a variation in one or more of these conditions affects the results. This cannot be done without an experimental plant, for no manager would be willing to have the regular course of operations disturbed in order to afford an object lesson to a group of students. In like manner the size of feed to rolls, the diameter, the distance between rolls, the spring pressure, and the manner of feeding are all important factors in securing quality and quantity of product. With commercial requirements to be considered, as is necessary in the usual plant, it is impossible for a student to learn experimentally the relative influence of these various factors.

It is very desirable to determine the relative capacity and efficiency of various screens; for instance, trommels and impact screens and especially new types recently introduced, for rarely does an individual plant employ both. For some reason one form or the other is adopted, and the possibility for the only proper comparison of value—that wherein both machines are working on the same material—is never afforded. As soon as a plant is in successful operation, the routine involving the rate of feed, the proportion of water, speed and stroke of machines is established and unless some radical change is decided upon in the practice these conditions are unvaried.

In the apparently simple process of gold milling the practice is so varied that unless it is possible, by means of an adjustable battery, to compare the different methods, students can form no true idea of the influence of these variations. It would be possible, in an experimental plant, to investigate every important detail of construction, to see how variations of all kinds affect the economy of operation, to appreciate the effects of various losses, and to determine their influence in operations on a commercial scale.

Perhaps the educational advantages which result from the possession of an experimental plant are nowhere more evident than in the improvement made possible in the thesis work of the seniors. Thesis subjects are now very limited in range; most of them may be grouped under one of two heads—the treatment of a specific ore, or a report on a mine. The former cannot be treated properly under existing conditions. The study of the amount and character of the work done by the various ore dressing machines is not possible at present, be-

cause no plant will permit the attachment of measuring devices which absorb useful power of direct cash value. So, too, a comparison of plate amalgamation with amalgamation by the Pierce device becomes impossible because we cannot compare the work of the methods on the same ore under similar conditions. An experimental plant like the one at the Colorado School of Mines, therefore, serves the purpose of a laboratory in a most practical and useful way.

Research Features.

Besides supplying the students of the School with a superb laboratory and thereby increasing the efficiency of their studies, the plant can be used as a research laboratory by the faculty and the alumni of the School. Problems of ore treatment applicable to ores of wide occurrence—problems which affect not only a single mine but a whole district—will be investigated and the results published.

The facilities of the plant also will be available to experts who desire to make investigations of their own. In addition to all this, floor space has been reserved for testing new devices. An inventor who wishes to perfect his invention can have all the facilities of power, water, floor space, ore supply and expert assistance at his command at a slight expense and will not be obliged to incur the heavy cost of equipping a plant for his one invention. The plant, then, will serve not only the needs of the School in an educational way, but will be a means of acquiring much information of great value to the mining industry.

Commercial Testing.

Commercial testing will be done in one of two ways:

(a) When ore is sent in to be tested the work will be done by the manager, assisted by the corps of assistants connected with the plant. The manager will make a report to the consignor and be responsible for the accuracy of the results. In no case, however, will such report state that the ore comes from any particular mine or locality, unless a member of the corps goes to the mine and takes the samples.

(b) Ore may be sent to the plant for testing and the owner may designate some expert who will have charge of the test and make a report only to the owner. In this case the expert in charge will be allowed the assistance of the manager and the regular corps at the plant. All the facilities of the plant will be at his disposal and he will be responsible for the accuracy of the results.

The second method, it is thought, will be most satisfactory to the mine owner and is, therefore, recommended. Facilities for the transportation of ore are afforded by the Colorado and Southern Railway and the Denver & Intermountain Railroad Co. Circulars of information, giving the cost of tests and other details, will be issued later.

Appropriations.

Two appropriations have been made for the erection, equipment and operation of the plant: $75,000 by the Seventeenth General Assembly and $50,000 by the Eighteenth General Assembly. The first has been expended in full and the second as yet only in part.

The Personnel.

Inasmuch as this plant differs in size, plan and scope from other commercial or educational plants now in existence, the drawing of the plans was a long and tedious operation. First, the faculty proposed, in a general way, their ideas to the consulting engineer, Frank E. Shepard, president of the Denver Engineering Works Company. He, assisted by Philo D. Grommon, a graduate of the School of the class of 1907, worked on the details in collaboration with Professors Traphagen and Haldane of the School.

Then, when nearly completed, the plans were submitted to two prominent engineers of Denver, D. W. Brunton and Philip Argall. Reduced copies of the plans were then sent to a large number of engineers in different parts of the [illegible] gestions and criticisms. Finally a prize of $50 was offered to the graduate of the Colorado School of Mines who should offer the best suggestion for their improvement. This prize was awarded to Wallace A. Stephens of the class of 1893.

The plant is organized as a department of the School with F. W. Traphagen as director, and William G. Haldane as manager in immediate and active charge of tests. Practical mill men and skilled mechanicians will be employed as the need for them becomes apparent. In no case will inexperienced students be allowed to carry on commercial tests. Such work will be done only by the regular experienced corps connected with the plant.

An advisory committee, consisting of the following men also has been appointed: D. W. Brunton, Denver, Colo., mining engineer; Philip Argall, Denver, Colo., manager Stratton's Independence; John Tait Milliken, Colorado Springs, Colo., consulting engineer; Thomas B. Crowe, Victor, Colo., superintendent New Portland Mill; William G. Swart, Denver, Colo., Western representative American Zinc Ore Separating Co.

Conclusion.

The possession of this plant enables the school to enter that broad field of usefulness that lies outside the distinct educational work of educating mining engineers. In every industry there are many problems, too large for the individual operator, which naturally can be solved best by the state or federal government. The government surveys the coast lines, maps the shoals, erects the lighthouses, prepares tables which show high and low water at all points on the coast; but, after supplying all this information, the government leaves the captain to manage his own ship.

The German government keeps a fostering eye upon all its industries. If any particular industry needs free raw material, the needed legislation is passed; if it needs a protective tariff until it can stand alone, such protection is enacted into a law; if a technical school is needed in which to train skilled workers, the government sees that such a school is established; if low freight or steamer rates are needed, the reductions are made; if better banking facilities are required, they are provided. And yet when all this is done by the government the individual operator must manage his own business.

Parallel with these illustrations is the work of the experimental ore dressing and metallurgical plant of the Colorado School of Mines. By means of this plant, knowledge of great theoretical and practical value to the ore dressing and metallurgical industries will be obtained, exhaustive tests will be made to indicate the character of the mill that should be erected to treat any particular ore successfully, but the operator must still build and manage his own treatment plant.

Victims of the Titanic Disaster.

Through the Titanic disaster metallurgy has suffered a heavy loss in the death of the following members of the profession:

Benjamin Guggenheim, one of the seven sons of Meyer Guggenheim.

H. Forbes Julian, chief metallurgist of the Butters Patent Vacuum Filter Co., a pioneer in the South African goldfields in the eighties, one of the authors of "Cyaniding Gold and Silver Ores."

Edgar J. Meyer, vice-president of the Braden Copper Company.

Ernest A. Sjostedt, well known to our readers through his electrochemical pioneer work carried out for the Lake Superior Corporation at Sault Ste. Marie (including the manufacture of ferro nickel in the electric furnace).

George D. Wick, of Youngstown, Ohio, formerly connected with various steel companies in the Middle West.

The Abuses of Our Patent System.*

BY DR. L. H. BAEKELAND
President of the American Institute of Chemical Engineers

A recent decision† of the Supreme Court upholding the right of patentees to dictate under what conditions a patented article shall be sold, or shall be licensed, has become the object of much criticism. One of our newspapers repeats the comment that this decision, interpreted to its extreme limits, so as to mean that "it would enable the patentee of a window frame to dictate that all the material of a house in which the frame was to be used, must be procured by him." But that argument overlooks the fact that nobody is compelled to buy that particular patented window and that the public at large can purchase any other window frame not patented, or of which the possession is not submitted to any restrictions.

The decision of the Supreme Court simply means that the owner of a patent, in selling or licensing under it, has the same privileges as the owner of any other private property. For instance, the proprietor of a lot can sell it with the restriction that if any house is to be built on it, the materials for this building shall be purchased from him. It all depends on whether the purchaser is willing to submit to these terms or prefers to forego acquisition under such restrictions To assail this decision of the Supreme Court, is to deny the elementary rights of private property, or to deny that a patent is private property.

Justice Lurton, in expressing the majority opinion of the Supreme Court, very correctly says: "When the patent expires, the public will be free to use the invention without compensation or restriction."

Outside of this limitation, why should restrictions be put upon ownership of patents, which do not exist for other forms of private property? An invention is the creation of something which did not exist before. Is the creator of this invention not entitled to undisturbed ownership, at least for a short period of 17 years, when the ownership of real estate, or other private property is undisturbed and continues for ever?

And yet, real estate always existed long before it got in the hands of private owners. Its mere possession does not imply any special merit, nor does the private ownership of real estate confer any benefit upon the community. Nevertheless, real estate can be left idle at the whim of the owner, who in the meantime, benefits by the enhanced value, the unearned increment, conferred upon his property through the enterprise of the community at large, and more specially by the enterprise of his immediate neighbors, who take the trouble and the risk to develop their own real estate, while he just remains inactive.

So that, in this and many other ways, the owner of real estate, or other private property, has an incomparably greater scope of unquestioned property rights than a patentee. Furthermore, these rights do not cease after 17 years, but continue for ever.

It is a significant fact that in many cases the persons who object most to patent rights are just those who have lived in surroundings, where industrial or intellectual development is least apparent.

In some parts of the country, the word "patent" is scarcely known, and the conception of a higher class of property than that which is merely acquired by inheritance or money purchase, is difficult to understand. On the other hand, the conception of intellectual property rights, is one of the symptoms of a higher state of civilization.

I may point out on this occasion, that the little state of Connecticut, takes out more patents than all the Southern States together.

Most people imagine that patent laws are for the exclusive benefit of inventors, and this regretable mistake leads to many misunderstandings. Were this opinion correct, patent laws would mean class legislation, and would be as unfair, as undemocratic, as unwholesome, and as dangerous as any other class legislation.

But the patent laws as framed under the Constitution of the United States, are primarily conceived for the benefit of the nation. No country has benefited more by its patent system than the United States. Compare the tremendous industrial development of such nations which have liberal patent laws, like the United States, Germany, and England, with that of the Latin countries, where patent laws are less favorable to the inventor.

There is one civilized country, Holland, which up till recently had no patent law whatever and allowed the unrestricted use of any invention. This ought to have been the Paradise of Infringers; it was easy enough to use freely in Holland processes patented in other countries, and to distribute from there infringing goods to all the countries of the world. Yet what was the result? Holland, with her highly developed commerce, her abundant money supply, with a race of intelligent and enterprising men, remained industrially undeveloped, and still ranks as one of the least among the industrial countries of the world. Why? Because there was no incentive to saddle oneself with all the risks and outlays of starting a new enterprise or of improving methods of manufacture, knowing beforehand, that in case of success, one's neighbor could simply do the same thing without any restriction whatsoever.

This standpoint that good patent legislation is for the benefit of the whole nation, is too often lost sight of and it behooves every good citizen of this country to help improve our patent laws and the administration thereof. A patent is simply a contract between the nation and an individual, the inventor. By that contract, the inventor discloses to the community at large, the results of his intellectual work; by doing so, he enables others to get acquainted with his work, and to improve thereon, and this stimulates further research, invention, and enterprise. You will find that newly disclosed patents are usually followed in rapid succession by several improvements thereon, conceived by others, but patterned on the original invention. The inventor, in disclosing his secrets, confers a benefit on the nation, and the nation, in return, gives him for a rather short number of years, the sole use of his invention—followed immediately afterwards by absolute confiscation in favor of the public. The period of this limited monopoly is none too long if we take into consideration the time it takes to develop an invention into commercial shape; in many cases, inventions reach the money-earning stage only after the patents on which they are based have expired. In the meantime the disclosures made by the inventor stimulate enterprise and further invention, and induce the ideal form of competition—competition by improvement.

So that, practically, the granting of a patent is simply a business contract between two interested parties; the nation and the inventor.

Up to this point everything goes well enough. Our patent laws, although not perfect, are generally considered as a model of good patent legislation; they were conceived in a broad and fair spirit, and the best answer to those who find too much fault with them is, that in all foreign countries, including Germany, whenever a modification has been made in their patent laws, the change has always brought them a step nearer to the American patent system.

The real trouble begins when this business contract between the nation and the inventor has to be enforced It is there that the patentee does not get "a square deal." After the inventor has faithfully performed his part of the contract, and has disclosed his invention to the nation, the nation hands him a "gold brick."

Woe, indeed, to the poor inventor who tries to enforce his rights against wealthy infringers, aided by skilful lawyers:

---

*A paper read on April 19th at a joint meeting of the New York Sections of the Society of Chemical Industry, the American Chemical Society and the American Electrochemical Society.

†Sidney Henry et al., vs. A. B. Dick Co., March 11, 1912, No. 20, October Term, 1911

His well engraved United States patent parchment may then become his certificate of entrance to the poor house, or to the lunatic asylum. All this tends to discourage invention by independent individuals and paralyzes the stimulation of invention our Constitution intended to promote by the patent law.

In other words, although the patent law of the United States is about as fine a piece of good progressive legislation as was ever conceived, its enforcement in the United States Courts, is subject to so many uncertainties, complications, delays, and to such horrible expenses, that the man with limited resources is at an inexpressible disadvantage.

If any one asks my advice, whether he should take out a patent or not, my invariable answer is: "Can you find the money to defend your rights in court? If not, do not waste any time or money on a patent."

Here, then, is an instance of a beneficient and well planned law, meant to be fair to everybody, which through absurd rules of practice and procedure, as sanctioned by American courts, has entirely deviated from its purposes. Meant to stimulate research and industrial development, it has merely become a pretext of playing bluff against bluff, tricks against tricks, by skilful acrobats of the profession of law.

As our patent law is used now, it is certainly a Godsend for large corporations, lawyers, and experts.

About three years ago, one of our most successful law practitioners, a candid man, declared publicly before the N. Y. Section of the American Chemical Society,* that as he was about to retire from business, he had no further hesitation in stating that in the many patent cases he had won for his clients, the latter seldom, if ever, got any settlements for damages, and if they did, it was a mere fraction of the fees he had collected from them for defending their case; he took the occasion to uphold to ridicule the absurd conditions prevailing in our courts, which make this possible.

Some experts reap just as golden a harvest by this state of affairs. Not so long ago, I overheard a chemist, whose specialty is to testify in patent cases, discussing with an opposing expert a patent case in which he was retained; his conversation was boisterous enough that any one present could hear it: "This is the most interesting patent we ever had in that line," he said. "Do you realize the fact that this means for you and me at least $5,000 a year for at least five years, and . . ." he significantly added, "this will give us an opportunity to learn much organic chemistry."

This, indeed, is the way some experts get their knowledge of chemistry: their clients pay for their tuition.

As to wealthy corporations, it has become obvious that the skilful handling of patent cases places them at an untold advantage against their smaller competitors. For them, a well-organized patent department is a reliable machine, where money is the lubricant. This machine, in its slow but sure grinding way, can reduce to pulp any of the smaller competitors. For large corporations, the maintenance of such a machine with a staff of lawyers and experts, is merely a small side expense. By its aid, they can bluff their weaker competitors into quick submission. If this is not successful, they can drag out a patent suit indefinitely, until the weak opponent, unable to bear the ever-increasing expenses, collapses and withdraws.

These tactics are well known and have been played successfully, whether it was to uphold a worthless patent, or to obtain immunity in case of infringement. In every case, the wealthy corporation is sure of the outcome of the game and plays "Heads I win, tails you lose."

Although these facts are sufficiently known by all who have practical acquaintance with patent litigation, the public at large is ignorant thereof, and cheerfully imagines that the inventor has a sure thing and that everything comes his way. We hear fairy tales of the fabulous wealth of inventors. I know many inventors, and I can tell you that very, very few of them ever obtained any important sum of money by their inventions, as such. If some have become rich, it is as manufacturers or as business men, and not merely by selling inventions. Most patents sold as such do not even repay the expenses involved in the preliminary work connected with them.

As matters stand now, the public does not get the benefit of our patent laws, and the law thus misses its highest purpose. Our degenerated rules of practice and procedure simply serve to strengthen the rich and mighty, who apparently disburse the funds for litigation, but in the end make the consumer, the public, pay the bill. But the consumer does not know this, and in his cheerful ignorance believes, in the meantime, that he has nothing to do with patent laws and patent litigation, so the matter does not interest him. On the other hand, many public spirited lawyers, disregarding narrow-minded professional interests, have spared no pains to expose this condition of affairs and have urged reforms.

Why, then, should this state of affairs have persisted so long? Why should our otherwise excellent patent laws have become so perverted in their applications? Simply through the sheer indifference of the directly interested parties: the public and the inventor.

As to the inventor, he is most to blame. I have met few inventors, who when asked for a remedy, did not come out right away with impractical or far-fetched cures. Most of them want to make a radical change in every department of our patent system, forgetting that it is easier to break down than to build up. Others suggest pet remedies of their own, but the worst of all is that no two inventors can agree on the subject. In justice to the inventors, I should mention that most of the lawyers I have met, are in the same predicament. In the meantime, the real fact is that very few reforms are necessary in order to remove the absurd conditions of our patent system, and these reforms can easily be acomplished if we only can agree on them. This I shall try to explain:

Formerly, all patent cases, on appeal, went by right, from the lower courts to the Supreme Court of the United States. The latter court not only rendered final decisions, but, what is more important, saw to it that the proper rules of practice and procedure were observed in the lower courts. The Supreme Court acted practically as a supervising body on our patent system, and lent considerable prestige to it. But through the rapidly increasing development of this country, the cases before the Supreme Court became so numerous that finally it took three to four years, after an appeal was filed, before a case could be heard. This amounted practically to a denial of justice, because some of the patents expired before their case was reached.

So in 1891, a remedy was inflicted, which has proved to be much worse than the ailment. Nine Circuit Courts of Appeal were organized, and each court, independently, can give *final* decision in patent cases. This has brought us into an intolerable condition of affairs. Indeed, each Circuit Court of Appeals can adjudicate only for its own circuit, and being independent of control of any other Circuit Court of Appeals, each court makes decisions as it thinks right, based upon the evidence submitted to this special court, and in accordance with its own view of the law. *So that we have now this absurd condition that some patents are valid in some parts of the country and invalid in others.* Any litigant with much money, who has been beaten in one circuit, can carry on his infringements with impunity in an adjacent circuit or drag on new suits forever and a day. While doing so, he knows very well that he can postpone a final decision as long as he is willing to pay his lawyers. But this is not the worst of the situation. Since the Supreme Court of the United States is no longer *by right* the final arbitrator in case of appeal, our whole patent system has lost the prestige and corrective influence of a final court supervising the faithful observance of proper rules of practice and procedure.

I am told that we have some good rules of practice formu-

* [illegible], 1909, vol. XII, p. 77.

lated long ago by the Supreme Court, but that since the practical elimination of this court in patent cases, lawyers and experts have acquired the habit of disregarding these rules or "waiving them by courtesy" for reasons of their own. I am even told that if these rules were honestly adhered to, the testimony of any patent suit could be ready for the court at the end of six months.

A bill for a Court of Patent Appeals has been pending now before Congress from year to year, and seems to meet with almost unanimous approval, even from lawyers. The only serious opposition seems to be on the part of some politicians, who do not like the idea of new judgeships being created, while their political opponents are in power. If this argument is kept up, the bill will never pass, unless we unite our voices to demand it.

Give us a Court of Patent Appeals which will render final decisions by which we can abide, instead of the absurd condition of affairs, where one Circuit Court of Appeals can oppose its decision to that of another. Give us a Court of Patent Appeals which shall formulate and maintain common-sense-rules of practice and procedure, and will stop the abnominable custom of taking unrestricted testimony without a presiding judge. Let us exclude all testimony which has nothing to do with the case, but which is entered as a trick to indefinitely prolong litigation; as a pretext to pad the records; as a technical dodge to drag on the case, and to defer judgment; as a means of saddling the poorer opponent with ever-increasing expenses until he staggers under the load and is ready to give up the fight, if in the meantime the term for which the patent has been granted has not expired.*

Let testimony be taken in open court as it is done in Germany, in England, and by other nations, where cases are tried and settled at relatively small expense and in a short time, instead of taking many, many years, as is often the case here. In Germany and in England, patent infringements are treated just like any other violation of property rights; with the same severity as though somebody had stolen or damaged another man's property.

While we are about it, let me mention the urgent need of a new Patent Office Building. That awkward Greek temple in F Street was acceptable enough when our country was so much smaller. It now has become a congested cumbersome unpractical fire-trap in which, some day, all the valuable records of pending and allowed patent cases will be destroyed. Whenever this occurs, and it may happen to-morrow, it will prove a real calamity for those of our manufacturers whose business is dependent on patents. That fire will give unusually unfair opportunities of making money to those who live and thrive on patent litigation.

The patentees of the United States have paid, up-to-date, to Uncle Sam, about $7,000,000 in excess of the expenses of the patent office. This fund has now accumulated to the credit of the patent office. Why should it not be used to construct a well equipped modern business building, where our patent records, which you and I have paid for, are kept in fireproof rooms? Such a building should be provided with all the equipment necessary for a thorough search. Many important references are not available in the patent office. It seems incredible, but complete copies of patents issued in some countries like Belgium, France and Canada, are lacking. If these lacking records had been available to the examiners, many invalid patents would not have been issued through sheer want of means of obtaining full information as to prior published disclosures. It is truly astonishing that under such handicaps, our overworked patent examiners have been able to furnish so much good work. An up-to-date patent building should possess also a complete laboratory, where simple chemical and physical questions can be demonstrated promptly and easily.

A very desirable reform in the practice of the patent office, would be the introduction of the German system of public objection to an "allowed" patent, before it is definitely "issued." In Germany, in Austria and in England after a patent has been examined and allowed by the examiner, the title and the claims are published and the copies of the text can be obtained from the patent office. Then during a period of two or three months, objections to the issue of the patent can be filed in writing, by anybody. Copy of the filed objections are forwarded to the applicant, who then has a few months to file an answer. In this way, the examiner has the benefit of a thorough public discussion of the subject before that patent is definitely issued. This involves a delay of several months in the issue of a valid patent, but this is a very small hardship, indeed, if one takes in consideration the fact that a patent issued after severe public contestation gains much in value by its record. Furthermore, this way of proceeding is now successfully used in the U. S. Patent Office for the registration of trademarks.

Some other useful reforms have been suggested, reducing the needlessly large number of appeals in case of interference.

Our interference rules may appear very logical in accordance with the conception that in the United States, a patent belongs to the first diligent inventor, independently whether he be the first patent applicant or not, as long as his invention has not been in commercial use before that period. To the uninitiated, this may seem an excellent safeguard to insure that the first inventor should receive the reward of his intellectual work. Unfortunately, any poor inventor, who has been through interference cases, knows that without much money an interference case becomes almost a hopeless proposition if he has to deal with wealthy antagonists. Indeed, I know of an interference case which has been going on for the last six or seven years, and which has already cost one of the contestants over $60,000. Even after the interference case is decided in one's favor, one has to take all the ordinary chances of further expensive infringement suits. Is this to the benefit of the public, for whom, primarily, our laws are created? Let us see: The public wants as early as possible a disclosure of any invention, and with that end in view, the patent law stimulates such disclosures by offering as reward 17 years of patent monopoly. Yet everybody knows that our interference system hopelessly delays the publication of an invention. Furthermore, our interference rules are in many ways a terrifying menace to the industries of the country.

For instance, a man applies for a patent. The patent is al-

---

*Judge Hough in giving his opinion in the famous Seldon case, where 36 huge volumes of printed testimony were submitted, took occasion to denounce our absurd methods of patent litigation, as follows:

"It is a duty not to let pass this opportunity of protesting against the methods of taking and printing testimony in equity, current in this circuit (and probably others), excused if not justified by the rules of the Supreme Court, especially to be found in patent cases, and flagrantly exemplified in this litigation. As long as the bar prefers to adduce evidence by written deposition, rather than viva voce before an authoritative judicial officer, I fear antiquated rules will remain unchanged and expensive prolixity remain the best known characteristic of equity.

"*But reforms sometimes begin with the contemplation of horrible examples*, and it is, therefore, noted that the records in these cases, as printed, bound and submitted, comprise 36 large octavo volumes, of which more than one-half contain only repeated matter, i.e., identical depositions with changed captions and exhibits offered in more than one case. In reading the testimony of one side in one set of cases there were counted over 100 printed pages recording squabbles (not accompanied with apparent personal rancor) concerning adjournments—and after arriving at this number it seemed unnecessary to count further. In many parts of the record there are not five consecutive pages of testimony to be found without encountering objections stated at outrageous length, which may serve to annoy and disconcert the witness, but are not of enough vitality to merit discussion in 2,000 pages of briefs. Naturally tempers give way under such ill-arranged procedure, and this record contains language uncalled for and unjustifiable, from the retort discourteous to the lie direct. And all this lumbers up the court record room, *while clients pay for it*.

"Even when the evidence in equity was taken up by written answers to carefully drawn interrogatories, the practice was not marked by economy or celerity, but stenography and typewriting, the phonograph and linotype have become common since our rules were framed, have made compression and brevity old-fashioned, increased expense and often swamped bench and bar alike by the quantity rather than the quality of material offered for consideration.

"Motions to expurge and limit cross-examination should have been made in these cases, though they are feeble remedies exposing counsel to personal reproach and rendering judges afraid of keeping out of evidence what they cannot (on motion at all events) understand. *But the radical difficulty of which this case is a striking (though not singular) example will remain as long as testimony is taken without any authoritative judicial officer present, and responsible for the maintenance of discipline and the reception or exclusion of testimony.*"

lowed and published. On the strength of this patent, a company is formed, which goes ahead, builds an expensive factory, and starts operations. Then frequently it has happened that an interfering patent application, which was not known to exist at the time the company was organized, embodies identical claims, and is put forward in objection to the published patent. This may invalidate the patent on which the company was formed, and thus stop and annihilate an enterprise which was begun entirely in good faith, and on a sound basis. Such a thing is impossible with the German system, where the first applicant, unless his application is based on fraud or theft, gets the patent, as long as no one else can prove prior use or prior public disclosure. Rigid examination, followed, after allowance, by a short period for public objection, makes the German proceedings relatively inexpensive, and gives added value and prestige to patents issued under this system.

It may be objected to this system that it induces filing an application before the invention is sufficiently ripe, but even with our system the same objection holds good. Furthermore, with our current methods, it is possible to file patents and let them pend for many, many years, and use these pending applications as a drag-net in which to catch any other patents which may be applied for by others, and by which to get the benefit of any practical developments or improvements which go on in the meantime; this was clearly demonstrated in the famous Selden case.

For deciding priority in purely scientific publications, it has been accepted, since the time of Humphrey Davy, that "priority of publication, unless in case of fraud, means priority of conception." This simple rule, if applied to the Patent Office system, would sweep away the most complicated and most expensive part of our Patent Office methods. At the same time, it would stop an interpretation of our patent law, which is decidedly dangerous and unfair to the unsuspecting public, and has no advantage to the inventor, unless he be rich, or unless he be propped by wealthy backers.

All these reforms, or improvements, whatever you want to call them, are relatively simple and might have been obtained long ago, if the real interested parties, the public and the inventors, had demanded them. If we unite in our demands, we can surely obtain them.

To the honor of the better class of lawyers, let me mention that the Patent Law Association of Washington, is doing good work to accomplish some much needed reforms. Lately, in conjunction with the American Institute of Chemical Engineers, and the Inventors' Guild, a start has been made in awakening the interest of our national engineering societies. Let us all join in this movement, and let us not overlook the fact that our legislators need as much education on this subject as the public at large. But if we try to suggest reforms, let us be practical and first concentrate our efforts on such reforms on which we all can agree. Let us avoid theorizing or dreaming. A perfect patent law will never exist, except perhaps in heaven, where all men are angels. After all men have become angels, patent laws, as well as other laws can be dispensed with. But we are still on earth and for a long time.

Remember that if there is much to criticise in our patent system, there exists the same chaos in our civil and criminal laws which badly need a general overhauling.

We chemists or engineers are apt to forget that though science, engineering, and all achievements based on exact knowledge and sound reason, have made immense progress in late years, our laws and the administration thereof, have advanced little beyond what they were two or three thousand years ago, so that they now are an anachronism badly adapted to our modern conditions of life. But most judges and lawyers, when they talk about dispensing justice, have acquired, like the Chinese Empire, the habit of looking backwards for "precedents," which for them will remain the most respectable and the most imposing arguments.

At this time, the immediate danger for our patent system, is that some Congressmen or Senators, ignorant of the real situation, but anxious to advertise that they want "to fight the trusts," will rush through bills which will work untold harm to our patent system and to the industrial progress of our country. Some of the many patent bills now before Congress sadly illustrate the unpreparedness of their happy-go-lucky originators. Our Congressmen and Senators should know that the best anti-trust remedies are those which stimulate individualism and private enterprise and nothing works so strongly to that effect than liberal patent laws provided such laws can be enforced by the patentee of moderate means instead of only serving the interests of wealthy corporations.

Why could this intricate subject of patent reform not be submitted to a commission created by the president? This commission, made up of competent men, should, before suggesting or endorsing reforms, consult with representatives of our national technical and engineering societies, as well as with manufacturers, business men, representatives of the patent office, and lawyers. A resolution to that effect, has recently been addressed to the President of the United States by the Inventors' Guild.

Symposium On Patent Reform

The last of the joint meetings of this season of the New York Sections of the American Chemical Society, the American Electrochemical Society, and the Society of Chemical Industry was held in the Chemists' Building, New York City, on April 19, and was devoted to a symposium on patent reform.

Three papers were presented, one, entitled "The Inventor, the Public, and the Law," by Mr. Walter F. Rogers, president of the Patent Law Association, of Washington, D. C.; another, entitled "Patents in Their Relation to the Chemical Industry," by Dr. Bernard Herstein, technical expert of the Tariff Board, Washington, D. C., and a third, entitled "The Abuses of Our Patent System," by Dr. L. H. Baekeland, president of the American Institute of Chemical Engineers.

Mr. Rogers discussed at great length the old British patent law and emphasized some differences in the United States patent law. He discussed the existing patent laws of this country on the basis of some important decisions and analyzed the provisions contained in the Oldfield patent bill now before Congress. He advocated the creation of a single court of patent appeals and thought it would be a good thing to systematize the information stored up in the Patent Office.

Dr. Herstein gave in his paper interesting statistics of United States patents relating to the chemical industry, emphasizing the predominance of foreigners in the field. He pointed out that 98 per cent of the German applications for United States patents are assigned to German firms and are not worked in this country. This, he thinks, works decidedly against the development of chemical industry in the United States. He suggested that this should be changed in future.

Dr. Baekeland's paper was considered by many *the* feature of the evening. It is printed in full on the preceding pages.

In the discussion which followed Dr. Maximilian Toch spoke of the abuses, emphasized by Dr. Herstein, which holds back the development of the chemical industry in this country.

Mr. W. H. Swenarton defended the existing law and practice in this country in general.

Mr. C. F. Carrier, Jr., discussed the troubles of the young inventor who does not know whether a certain field is open or not even if he has a patent, and emphasized that the inventor's title should be made secure before a patent is issued.

Mr. John C. Pennie, in a written communication, called attention to the imminent danger of the passage of harmful legislation by the present Congress.

Dr. Baekeland replied to Mr. Swenarton's defense of existing patent conditions with strong effect.

The meeting lasted almost to midnight.

Resistivity Determination of Magnesium by Kelvin Double Bridge Method.

By F. F. Northrup

The **object of the measurement** was to determine the resistivity and temperature coefficient of a bar of magnesium metal in the temperature range, 20° C. to 155° C.

The **precision sought** was 1/5 of 1 per cent in the final result.

The **sample** selected for the measurement was a bar of magnesium which had been accurately shaped in a milling machine to have a rectangular cross-section. Its dimensions were determined with a micrometer caliper and a comparator.

Length of bar over all = 35.60 cms.
Length of bar between potential points = 21.883 cms.
Breadth of bar = 1.412$_7$ cms.
Thickness of bar = 1.444$_8$ cms.
Cross-section of bar = 2.041$_1$ cms^2.
Weight of entire bar = 78.760 grams.
Density of bar = 1.723$_2$.

The potential points were located by drilling two holes in the bar each about 6.8 cms. from an end of the bar. No. 24 brass wire pins were driven in these holes and to these the potential leads were soldered.

The current terminals were fastened to each end of the bar by means of small brass clamps having jaws like a vise. Heavy copper leads were soldered to these brass clamps. As the jaws of the clamps gripped the bar upon opposite sides the current entered the bar so that the stream lines of current very soon became parallel with the length of the bar and were assumed to be almost perfectly so at the potential points.

The chemical analysis of the sample was made by Mr. H. E. Rankin, who reports upon it as follows:

"After the superficial coating of oxide had been removed samples of from forty to fifty grams were taken from the bar of magnesium and submitted to a most careful qualitative and quantitative chemical analysis. No statement can be made as to the absolute accuracy of the determinations since one can never be sure that the impurity sought for is not occluded by the precipitate. However, all precipitates were carefully examined, purified, and in many cases reprecipitations made to insure purity. More than particular attention was paid to the searching for traces of carbon, silicon, chlorine, aluminium, nitrogen, and the oxide dissolved in the metal, since these are the impurities ordinarily found associated with magnesium.*

The treatment of the metal with nitric acid resulted in a perfectly clear solution with no residue. No traces of impurities could be detected in this solution by the ordinary procedure in qualitative analysis or by special methods. Such a result, however, might be expected, since magnesium can be obtained according to Deville, Caron and Sonstadt in a very pure state by distillation.†

"In the quantitative determinations nitric acid solutions were used. The magnesium was precipitated as magnesium-ammonium phosphate and ignited to the pyrophosphate in which form it was weighed. A searching examination was made of all such precipitates and the solutions from which they were separated. Some comparison determinations were made from hydrochloric acid solutions‡ with practically no difference in the results as shown by the following figures:

Average per cent Mg. in HCl solution..... 100.03%
Average per cent Mg. in HNO_3 solution..... 99.97%
Average per cent of magnesium..... 100.00%

"It seems reasonable, therefore, within the limits of experimental error, to consider the bar of magnesium to be free from all detectable impurities."
